(*b*) we neglect any solvation energy of e^-, which will be small in the case of C_6H_{12}/H_2O vapour, and (*c*) the shape of the temperature-sensitive part of the curve is not closely established, although any change based on the existing data will not have a major effect on the estimated values for ΔH. The data of Kebarle and Hogg[3] indicate that each hydration step in the vapour phase is exothermic by ~ 17 kcal/mole, so that in the foregoing representation $n = 6–7$. This is probably a reasonable estimate on the basis of enthalpy changes, as additional H_2O molecules will not contribute significantly to the solvation energy. Moreover, additional molecules could be removed from the hydration shell at temperatures $< 240°$ C without resulting in a distribution of hydrates containing enough lower members to give an observable contribution from reaction (2) on charge neutralization. These data, together with those of Kebarle and Hogg, suggest that the H_3O^+ ion with one or possibly two molecules of hydration can give 2 H atoms and 1 OH radical in the vapour phase, on charge neutralization.

Separation of Oxygen Isotopes by Gas Chromatography

Separation of some volatile isotopic molecules can be achieved either by gas solid chromatography on packed columns[1] or by gas liquid chromatography on capillary columns[2]. The small differences in vapour pressure of isotopes require columns with a high number of theoretical plates, which is more easily realized with open tubular columns.

Working at low temperature is recommended as the vapour pressure differences between isotopic compounds are usually enhanced; however, the use of partition chromatography is limited as it requires the stationary phase to be liquid. The use of adsorption capillary columns, recently reported[3], offers the advantage of working in any temperature range, and of obtaining the high resolving power such as is required for isotopic separations.

Glass capillaries for gas solid chromatography, prepared according to a method previously described[4], have been used for the separation of the isotopic molecules, oxygen-16/oxygen-18.

To prepare adsorbing surfaces, the inner walls of the glass capillaries were etched with an alkaline solution (20 per cent sodium hydroxide) for 6 h at 100° C, and washed to neutrality. The column was dried and activated under a flow of nitrogen at 200° C for 48 h. An internal layer of active silica (about 10μ thick) was uniformly distributed inside the column (170 m long and 0·28 mm internal diameter). The efficiency of this column, measured from the oxygen peak at the working conditions of the chromatogram shown in Fig. 1, is approximately 350,000 theoretical plates.

A low-temperature thermostat was used, which consisted of a metallic case containing the capillary column, a small electric heater, and a fan. The case was immersed in a Dewar flask containing liquid nitrogen. By changing the current supplied to the heater with a variable transformer it was possible to regulate the temperature inside the thermostat within the range $-190°$ to $-120° \pm 1°$ C. The temperatures were measured with an iron-constantan thermocouple. Pure nitrogen dried in a molecular sieve trap was used as carrier gas. An electron capture detector, operating in the d.c. system, was used to detect the presence of oxygen. An additional flow of 50 ml./min of nitrogen was added at the exit of the column as scavenging gas. By means of a special valve and a splitter at the column inlet, 0·1–0·3 ml. samples of each component were introduced in the ratio of approximately 1 : 100.

Table 1 shows the operating conditions and the results obtained at different temperatures. Retention volumes have been corrected for the 'column dead volume' measured from the oxygen peak obtained at room temperature. The values of the retention volumes ratios of the two isotopic molecules are compared with the ratios of the vapour pressures at the same temperatures[5].

Table 1

Temperature (° K)	Pressure (mm Hg)	Flow rate (ml./min)	$V_{R_{16}O_2}$ (min)	$V_{R_{18}O_2}/V_{R_{16}O_2}$	$P_{^{16,16}O}/P_{^{16,18}O}$
91·2	12·5	0·5	55·8	1·0036	1·0053
84·2	90	0·45	99·3	1·0065	1·0065
80·2	130	0·72	176	1·0107	1·0073

From a plot of a log of these ratios against $1/T$, it is possible to obtain the differences in the enthalpy and entropy changes between the isotopic species; for the chromatographic process these are, respectively:

$$\Delta H_{18_{O_2}} - \Delta H_{16_{O_2}} = 7·79 \text{ cal}$$

$$\Delta S_{18_{O_2}} - \Delta S_{16_{O_2}} = 0·1 \text{ e.u.}$$

From the data shown in Table 1 it is apparent that at the higher temperature the retention volume ratio for oxygen-18/oxygen-16 is smaller than the vapour pressure ratio for the mixed molecule, and consequently the separation obtained by gas chromatography is less than that expected from the relative volatilities; however, at lower temperature the differences are larger, and the separation factors achieved by gas chromatography increase more rapidly than the vapour pressure ratios. This behaviour might be explained by the fact that at low temperatures the differences in the heats of adsorption have a larger effect than the differences in the heats of condensation.

This research has been supported by a grant of the National Research Council (C.N.R.) of Italy.

BIOCHEMISTRY

Evidence of Complex Formation between Chlorpromazine and Different Xanthene Dyes

The formation of charge-transfer complex between flavin mononucleotide (FMN) and serotonin has been examined in detail[1], as a good example for a complex of biochemical interest and of characteristic colour change. Chlorpromazine can also form complexes with FMN and rhodamine *B*[11,12].

It is also known that at low temperature the xanthene dyes and ascorbinic acid form in pyridine a rather stable semiquinone[2]. This product results in the appearance of a new band in the absorption spectra of the stains at 410–430 mμ. This new band represents a blue shift.

The xanthene dyes are adequate substances to evoke different forms of photosensitization[3] for one photo-induced muscular contraction[4–7] which can be well inhibited by chlorpromazine[7].

We observed characteristic colour changes when chlorpromazine and eosin *Y*, erythrosin *B* or rose bengal were mixed. The colour change has been observed in water and in 96 per cent ethanol.

The change of the spectral absorbancy is demonstrated by the difference of extinction between the stain and stain–chlorpromazine mixture solutions in Figs. 1 and 2. The shape of the curve in ethanol suggests a solvent effect.

The peak of the new substance is shifted in a redward direction with about 30–40 mμ. In the case of rose bengal and erythrosin it is at 570 and 555 mμ respectively, so these substances cannot be identical with the semiquinone demonstrated by Zepalov *et al.*[2]. The low ability of eosin to react with chlorpromazine causes difficulties in measuring the spectral changes in the chlorpromazine–eosin mixtures.

As these stains can emit fluorescence at 580, 560 and 542 mμ respectively, we measured the fluorescence emission of the stains, exciting them with a mercury lamp (Beckman fluorescence attachment). We were able to measure the quenching of the fluorescence at the aforementioned wave-lengths. The quenching is demonstrated in Fig. 3 plotted against concentration of chlorpromazine. The rate of the quenching is in direct relationship with the photo-sensitor ability: rose bengal > erythrosin > eosin.

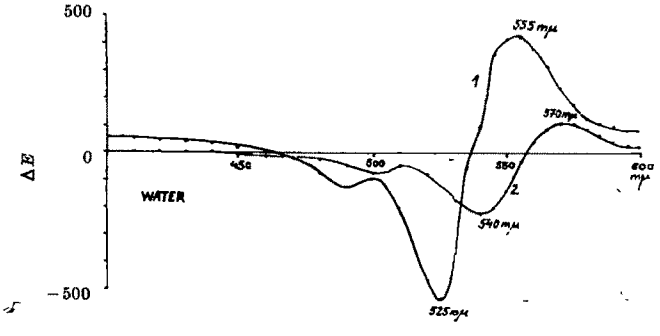

Fig. 1. Difference between extinction of the stain–chlorpromazine and stain solutions in water plotted against wave-length. Curve 1, *E*[25 μg/ml. erythrosin + 25 μg/ml. chlorpromazine], *E*[25 μg/ml. erythrosin]; curve 2, *E*[10 μg/ml. rose bengal + 10 μg/ml. chlorpromazine]; *E* [10 μg/ml. rose bengal]

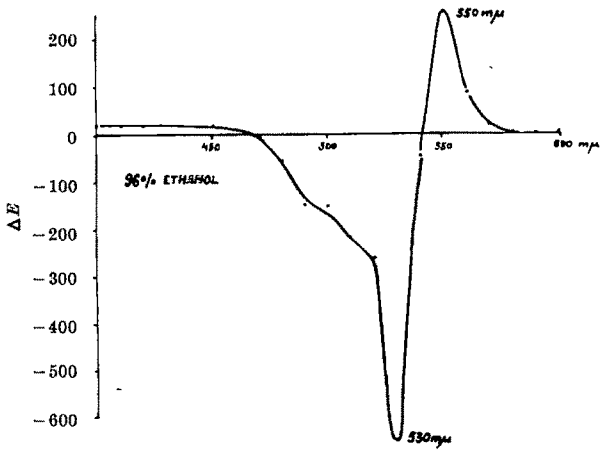

Fig. 2. Difference between extinction of erythrosin–chlorpromazine and erythrosin solutions in ethanol of 96 per cent plotted against wave-length. 25 μg/ml. rose bengal and 500 μg/ml. chlorpromazine

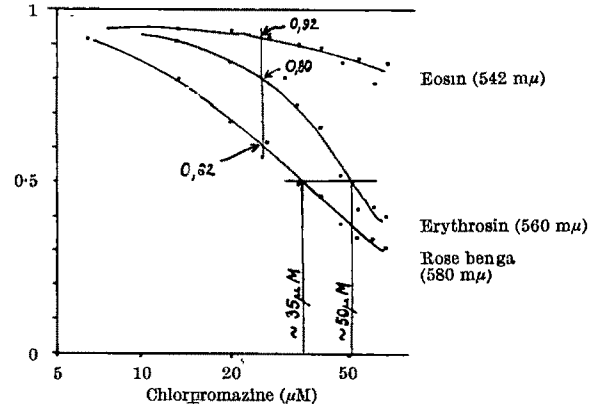

Fig. 3. Quenching of fluorescence of the stains at their peak by chlorpromazine plotted against chlorpromazine concentration Concentration of the stains was 25 μM Quenching of 50 per cent is at about 35, 50 μM chlorpromazine concentration in the case of rose bengal and erythrosin respectively. Quenching at 1 mol. ratio is 0 92, 0 80, 0 62 in the case of eosin, erythrosin and rose bengal respectively

The first investigations were carried out in filtered lake water, as the inhibitor effect of chlorpromazine against xanthene dyes-sensitized contraction had also occurred in water. Our chlorpromazine preparation in water above 35 μg/ml. showed opalescence, indicating its bad dispersity, so we measured the optical properties below the critical concentration and against chlorpromazine-blank. In ethanol the colour changes are smaller, and bleaching is higher than in water. These factors favour another reaction-kinetics.

Considering the observed phenomena two alternatives emerge. The bad solubility of chlorpromazine might indicate an adsorption connected with colour change. The good stability of the new complex after having mixed the participating substances contradicts this mechanism. There is another phenomenon which proves the formation of a new substance. One can observe two bands in the fluorescence emission spectrum of the rose bengal, at 580 and at 460 mμ. In the presence of chlorpromazine the fluorescence at 460 mμ increases and at 580 mμ decreases. The increase and decrease of fluorescence plotted against wave-length are demonstrated in Fig. 3. The decrease of fluorescence at 580 mμ is probably connected with the loss of the original stain concentration and with the increase of absorbancy of the new substance just at 580 mμ. The increase in fluorescence at 460 mμ probably originates from the complex substance alone or from chlorpromazine.

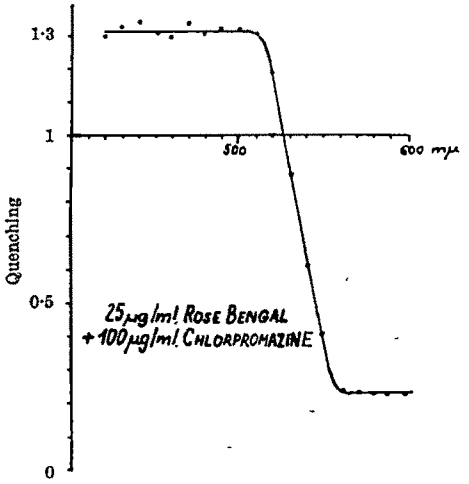

Fig. 4. Quenching and amplification of fluorescence of rose bengal by chlorpromazine plotted against wave-length

It is known that if flavin and adenine are attached similar shifts and quenching occur in the absorption and emission spectra of the flavin[8]. These changes are attributed to the formation of a complex[9]. The complex formation between FMN and dihydrothioctyl was found to be connected to similar spectral changes[10].

These changes were demonstrated as charge-transfer complex because no electron spin resonance signal was obtained[10].

Therefore, we suppose that the lilac coloration of the xanthene dyes–chlorpromazine mixture is due to the formation of charge-transfer complex and that there is sufficiently strong interaction between the participating substances to abolish the photosensitization by stains[7].

Is the Antihaemophilic Globulin a Protein ?

The antihaemophilic globulin (AHG), in electric fields migrating in the β_2-fraction, and being precipitated from blood plasma by alcohol in fraction I (ref. 1) is generally considered to be a protein. Our laboratory has for a number of years been occupied with the problem of its purification[2,3] with the final aim of contributing to the elucidation of its structure, and, if possible, to the mechanism of its interaction with other blood-coagulation factors.

For a long time ECTEOLA-celluloses of various capacities were used in the purification experiments; later on we turned to DEAE-celluloses because of their greater protein-binding capacities. During these experiments it became clear that the higher the ion-exchange capacity, the higher the salt concentration which could be used during the absorption and washing stages of the chromatographic procedure, without the AHG leaving the column unadsorbed. In other words, AHG could still be adsorbed at relatively high salt concentrations, which permitted most of the proteins and other impurities to flow through the column unadsorbed. A rather high ion-exchange capacity, namely, 3·2 m.equiv./g, was then found in DEAE–'Sephadex *A*–25' (coarse). This enabled us to work at a sodium chloride concentration of 1·6 per cent. As long as the columns were operated at about their maximum AHG-binding capacity (fraction I from 100 ml. plasma per 15 g of DEAE–'Sephadex') the preparations obtained showed absorption spectra similar to those of proteins, but lacking the peak at 280 mμ (cf. ref. 4). When the amount of plasma per column was decreased, the protein character of the absorption spectrum disappeared altogether (Fig. 1).

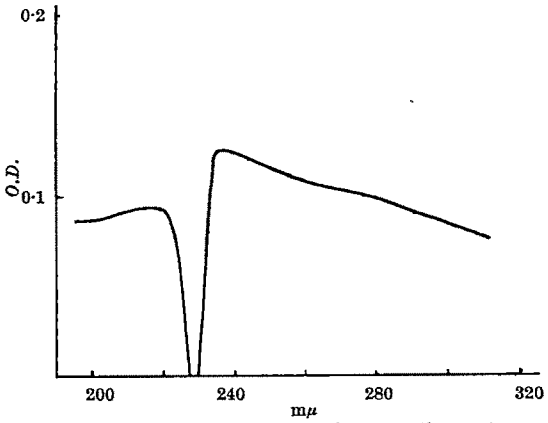

Fig. 1. Absorption spectrum of an AHG-preparation; 1·5× normal activity

Nevertheless, such preparations had biological activities of about 150 per cent (normal plasma = 100 per cent). Some of them were hydrolysed with 5·7 N hydrochloric acid at 105° C for 18 h. Two-dimensional paper-chromatograms[5], developed with ninhydrin, showed the presence of only 4 faint spots, which could not very easily be identified with any of the well-known amino-acids.

Since the homogeneity of the AHG-preparations is by no means certain, speculations about the amino-acids and the absorption spectra are not helpful; further investigations are necessary to clear up the present situation.

I thank Prof. Dr. S. van Creveld and Prof. Dr. W. H. H. Tegelaers for their advice.

N-Hydroxy-2-fluorenylbenzamide, an Arylhydroxamic Acid with High Carcinogenic Activity

For investigations of the mechanism of action of carcinogenic arylhydroxamic acids we have prepared the new hydroxamic acid, *N*-hydroxy-2-fluorenylbenzamide (*N*-OH-2-BAF) (I*a*), an analogue of the carcinogen, *N*-hydroxy-2-fluorenylacetamide (*N*-OH-2-AAF) (I*b*). We have tested this compound for its carcinogenicity and

I (*a*) $R = C_6H_5$ (*b*) $R = CH_3$ II

found it to be an extremely active agent. We wish to report here the results of tests in which the carcinogenic activities of *N*-OH-2-BAF, of its parent amide, *N*-2-fluorenylbenzamide (BAF) (II), and of *N*-OH-2-AAF (ref. 1) for the young female Holtzman rat have been compared.

N-OH-2-BAF, m.p. 187°–190° C (corr.), was prepared either by the partial catalytic (5 per cent Pd-C) hydrogenation of 2-nitrofluorene in ethyl acetate in the presence of benzoyl chloride or by the benzoylation of 2-fluorenylhydroxylamine[2] in pyridine. *N*-OH-2-BAF was purified through its copper chelate which formed when the compound was treated with cupric acetate in methanol. The chelate was decomposed with hydrogen sulphide in the usual manner. The compound was characterized by the elemental analysis (calculated for $C_{13}H_{15}NO_2$: C, 79·73; H, 4·98; N, 4·65; found: C, 79·44; H, 4·88; N, 4·77) and by its ultra-violet (λ_{max}^{MeOH} 303 mμ (ε, 21 100) with shoulders at 295 and 283 mμ; λ_{min}^{MeOH} 242 mμ (ε, 8 300)) and infra-red spectra (potassium bromide; ν_{O-H} = 3,160 cm^{-1}, $\nu_{C=O}$ = 1,610 cm^{-1}). BAF, m.p. 223°–224° C (corr.), was prepared by the benzoylation of *N*-2-fluorenamine in pyridine[3]. *N*-OH-2-AAF, m.p. 147°–148° C (corr.), was prepared by the standard procedure[1]. The carcinogenicities of the compounds were tested on young female albino rats (purchased from the Holtzman Rat Co., Madison, Wisconsin) which initially weighed 50–70 g. The animals were caged individually at 26° C and maintained on a 20 per cent casein diet[4], except those injected with *N*-OH-2-AAF, which were fed a grain diet[1]. The weight of each rat was recorded before each injection and once weekly after the injections had been completed. The compounds (4·5 mg/100 g body-weight) were administered intraperitoneally three times weekly for 4 weeks as a suspension in saline containing 1·75 per cent gum acacia[1]. Because of the short survival time of the rats treated with *N*-OH-2-BAF on this schedule 6 animals were given the compound (4·5 mg/100 g body-weight) twice weekly for 6 weeks by intraperitoneal injections in a separate series. Autopsies were performed on all animals immediately after death or killing. The tumours and certain other tissues (liver, kidney and lungs) were fixed in buffered formalin and sectioned. The sections (5–6μ thickness) were stained routinely with haematoxylin-eosin.

Table 1. CARCINOGENICITY OF *N*-2-FLUORENYLBENZAMIDE (BAF), *N*-HYDROXY-2-FLUORENYLBENZAMIDE (*N*-OH-2-BAF), AND *N*-HYDROXY-2-FLUORENYLACETAMIDE (*N*-OH-2-AAF) FOR THE YOUNG FEMALE HOLTZMAN RAT

Compound administered*	No. of rats used	Average amount of compound administered (mmoles/rat)	No of rats surviving At 8 weeks	No of rats surviving At 20 weeks	No. of tumour-bearing rats†	% Tumour incidence of rats surviving 8 weeks
None	12	—	12	12	0	0
BAF	12	0·20	12	12	1 (1)	8
N-OH-2-BAF	17‡	0·15	8§	3	8 (12)	100
N-OH-2-AAF	12	0 23	12	11	11 (26)	92

* All compounds (4·5 mg/100 g body-weight) were administered intraperitoneally in 0·9 per cent sodium chloride containing 1 75 per cent gum acacia (ref. 1).
† The numbers in parentheses are the total number of tumours
‡ Eleven rats received *N*-OH-2-BAF three times a week for 4 weeks and 6 twice a week for 6 weeks.
§ Nine animals died before 8 weeks with no incidence of tumours (average survival time equals 4·5 weeks).

The data of Table 1 show that tumours were present in all animals which received *N*-OH-2-BAF and which survived 8 weeks. 8/8 rats had intraperitoneal sarcomata which occupied the entire intraperitoneal cavity in several instances. Ascites were present in all these animals and hydronephrosis from ureteral obstruction was observed in two cases. The tumours invaded the intestinal wall, diaphragm, myometrium, lymph nodes and vascular spaces. Metastasis to the lungs was noted in one instance. The histological appearance of the tumours was similar to that of the intraperitoneal sarcomata obtained in adult male and female rats with greater amounts of *N*-OH-2-AAF than the quantities of *N*-OH-2-BAF used in the present experiments[1]. 3/8 Rats developed mammary tumours similar in appearance to the adenofibroma of the rat breast[5]. In contrast, the rats receiving BAF were free of tumours except for one animal which had an adenofibroma of the mammary gland. The low carcinogenicity of BAF observed here agrees with the assessment of its carcinogenicity by other workers[6]. 11/12 rats receiving *N*-OH-2-AAF had mammary tumours as previously described by Miller *et al.*[1]. No intraperitoneal sarcomata were noted in the young female rat with this dosage of *N*-OH-2-AAF confirming the results of Miller *et al.*[1]. Judging from the tumour incidence and the amounts of compound which induced neoplasia, *N*-OH-2-BAF appeared to be as potent a carcinogen as *N*-OH-2-AAF. In addition, *N*-OH-2-BAF depressed the rate of growth of the rats after the first injection and the depression persisted throughout the lifetime of the animals (Fig. 1).

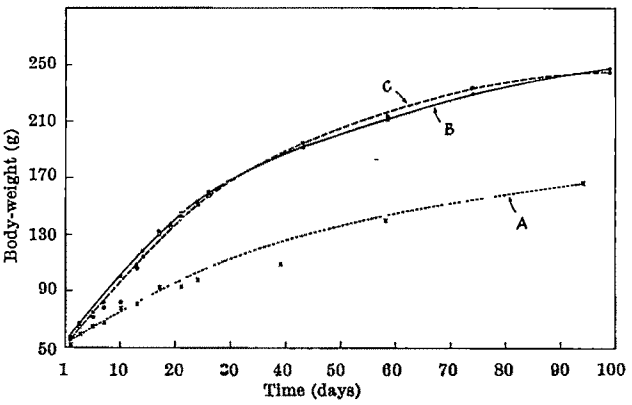

Fig. 1. The average weight gain of young female rats receiving *N*-hydroxy-2-fluorenylbenzamide (curve *A*) and *N*-2-fluorenylbenzamide (curve *B*) intraperitoneally in saline containing 1·75 per cent gum acacia at a dose-level of 4 5 mg of compound/100 g body-weight. Curve *A* represents the average weight of 17 rats at 7, 14 and 28 days, respectively, and of 12, 8 and 5 rats at 42, 56 and 90 days, respectively. Curve *C* is the average gain in weight of rats injected with the vehicle

These experiments indicate that an aromatic amide of low carcinogenicity (BAF) can be converted into a highly potent carcinogen (*N*-OH-2-BAF) by synthetic *N*-hydroxylation. We have reported previously that a non-carcinogenic metabolite of *N*-2-fluorenylacetamide, *N*-(7-hydroxy-2-fluorenyl)-acetamide[6,7], was transformed into the carcinogen, *N*-hydroxy-(7-hydroxy-2-fluorenyl)acetamide, by synthetic *N*-hydroxylation[8]. These results show clearly that arylhydroxamic acids are more active carcinogens than the respective parent amides, and they support the view that *N*-hydroxylation is essential in the metabolic generation of a molecular species which is more carcinogenic than the administered aromatic amide[1,8].

This work was supported, in part, by grant *CA*–02571 from the National Cancer Institute, U.S. Public Health Service.

Components of the Spore Wall of *Pithomyces chartarum*

The cell walls of fungi are known to contain large quantities of carbohydrate material, mainly composed of polymers of glucose, galactose, mannose and amino-sugars[1,2], but only in a few cases have the components been isolated from the walls and characterized. It is generally accepted that glycoproteins account for a considerable portion of the wall material in yeast[3], as they do in the hyphal walls of the filamentous fungus, *Pithomyces chartarum*[4]. Very little is known about the composition of spore walls; those of *Aspergillus oryzae* contain carbohydrate, protein and nucleic acid[5], and those of *Mucor rouxii* have carbohydrate, protein, lipid and pigment[6], the carbohydrate having been isolated as glucan, mannan and chitosan.

Spores, a gift from Dr. A. Smith, Ruakura Animal Research Station, New Zealand, were broken by disruption with glass beads in a Braun disintegrator (Shandon, Ltd., London), freed from cytoplasmic contamination by repeated sedimentation in 0·1 per cent sodium chloride and isolated after exhaustive dialysis followed by freeze-drying. The black pigmented product was shown to contain 45 per cent carbohydrate, 3·6 per cent bound hexosamine and 18·8 per cent protein (Table 1). Treatment with 10 per cent trichloroacetic acid failed to extract any material from the isolated walls (in contrast 15 per cent of the hyphal wall of the same organism was solubilized as phosphoglycoprotein under the same conditions[4]). Isolation of the cell wall components was achieved by extraction with anhydrous ethylenediamine at 37° C. On removal of the solvent, two chemically distinct fractions were obtained (Table 1), one soluble in ethylenediamine and soluble in water, *SWA* (4 per cent), the other soluble in ethylenediamine but insoluble in water, *SWB* (16 per cent). A residue, insoluble in ethylenediamine, was also recovered, *SWR*. Each fraction was shown to contain carbohydrate and protein. In addition the final residue contained all the wall pigment. The nature of the carbohydrate portion of each fraction was shown by examination of the acid hydrolysates using thin-layer chromatography. Each fraction contained glucose and glucosamine; in addition, *SWA* contained galactose and mannose. Ion-exchange chromatography of the acid hydrolysates of the three fractions showed the presence of fifteen amino-acids, in variable amounts, namely, asp, glu, ser, gly, ala, leu, ile, pro, val, lys, arg, thr, phe, his, met. Electrophoresis of the two extracted fractions on glass-fibre paper using formic–acetic acid buffer, 0·05 M, *p*H 2·0, indicated co-migration of the carbohydrate and protein in each case. In addition, *SWA* was chromatographed on a DEAE-cellulose column. Two fractions were obtained, one of which was not absorbed in *tris*-hydrochloric acid buffer, 0·001 M, *p*H 8·1, the other being eluted with the same buffer, 0·05 M, *p*H 8·1. The two glycoprotein fractions which were isolated from the spore walls were found to contain the same sugar and amino-acid components as the corresponding glycoproteins similarly extracted from the hyphal walls of the same organisms—the main difference being that the spore wall components contained less carbohydrate and more protein than the hyphal wall fractions. No evidence was found for the presence of the highly phosphorylated type of glycoprotein existing in the hyphal wall[4].

Table 1. Composition of Spore Wall Fractions

PHYSIOLOGY

Reflex Activation of the Soleus Muscle of the Decerebrate Cat by Vibration

The primary afferent ending of the mammalian muscle spindle is highly sensitive to vibration[1–4]. In the presence of fusimotor activity it may discharge an impulse on each cycle of vibration applied to the muscle tendon, for vibrations of frequencies up to 300–400/sec and of amplitudes of a fraction of a mm (refs. 2 and 4). In the decerebrate cat, maintained stretch of an extensor muscle usually evokes from it a prolonged reflex contraction—the classical stretch reflex[5]. This reflex is generally believed to depend on the excitation of the primary endings of the spindle by the stretching of the muscle. Thus, it might be anticipated that vibration would also evoke a 'stretch reflex' in the decerebrate cat. The present experiments show that it does, indeed, do so.

The experiments were carried out on cats decerebrated under deep ether anaesthesia by transecting the mid-brain between the colliculi. The soleus muscle was investigated and the technique was generally similar to that described earlier[6]. The vibration was applied to the muscle tendon by connecting it to a vibrator (Pye-Ling, *V* 50), the steady current through which was modulated sinusoidally. The amplitude of vibration was determined by microscopic observation using a micrometer eyepiece. The contraction of soleus was recorded by connecting its tendon to an isometric myograph which was mounted on the end of the vibrator and through which the vibration was transmitted. The myograph utilized a semi-conductor strain gauge. Its maximum frequency of response was deliberately restricted to about 25/sec by electrical low-pass filters. This served to remove from its output the tension changes resulting directly from the vibration. The electrical activity of soleus was recorded from a pair of wires placed on its belly about 3 cm apart; virtually all the nerves in the leg, thigh and hip regions were severed except for that to soleus, so there was little doubt that the recorded activity did arise from soleus[6]. The leg was held by drills through the distal ends of the tibia and of the femur. The summed compliance of this fixation and that of the moving element of the vibrator was about 1 mm/kg; this comparative lack of rigidity is immaterial for the demonstration of the present effects.

Fig. 1 shows the typical reflex response of soleus to vibration. The initial length of the muscle was a few mm short of the maximum extension possible physiologically, but in this case there was no appreciable maintained tonic stretch reflex; the initial tension was 80 g wt. Vibration of 10μ amplitude at 200/sec elicited a contraction of 100 g wt. accompanied by appreciable electrical activity of the muscle. 100μ amplitude vibration caused a contraction of 500 g wt., accompanied by a massive

electrical discharge. There was no doubt that these effects were due to reflex excitation of the muscle, for they were abolished by cutting its nerve or by stimulating the central end of the cut peroneal nerve which reflexly inhibits the soleus motoneurones[6]. Fig. 2 shows this reflex inhibition of the response to vibration, demonstrating that the contraction cannot have been due to direct excitation of the muscle fibres by the vibration; following the inhibition there was a 'rebound' increase in the contraction of the muscle. It can be assumed that the receptors responsible for at least the major part of the vibration response lie in the muscle itself, for the rest of the hind-limb was widely denervated. More significantly, similar vibration applied to the denervated tibialis anterior muscle did not produce contraction of soleus, showing that the response was not due to spread of the vibration to receptors in the pelvic region which had not been completely denervated.

High-speed recording of the electromyogram showed that the minimum latency of the response was usually just under 10 msec from the beginning of the vibration when its amplitude was large (100μ). On cessation of the vibration there was always an abrupt decrease in the reflex within 10–20 msec. Sometimes, however, the contraction did not immediately return to its previous level, but remained larger for 1–2 sec. The reflex response to vibration was found for frequencies of vibration from 50 to 500/sec. Increasing the amplitude of vibration at any frequency increased the response up to an approximately constant maximum tension. Surprisingly, altering the frequency of vibration had relatively little effect on the value of this maximum. When the vibration was applied for periods of up to a minute, the reflex usually persisted throughout. The reflex still occurred after ablation of most of the cerebellum, including the whole of its anterior lobe, but it was abolished by section of the spinal cord at *C*1. It was also abolished by an anaesthetic dose of 'Nembutal' (40 mg/kg). In all this, its behaviour parallels that of the tonic stretch reflex elicited by maintained extension of the muscle. Thus, vibration appears to be another way of activating the tonic stretch reflex. In other experiments maintained reflex responses to vibration were seen also for the gastrocnemius and tibialis anterior muscles.

There is little doubt that the primary endings of the muscle spindles were being excited by the vibrations used[2,4], and this provides an adequate explanation for the observed effects. However, only direct recording of their discharges can show whether or not other muscle receptors are also excited, and thus whether they too may play some part in the observed reflex responses. If vibration should activate the primary endings virtually alone[2], then it would prove a useful tool for extending the investigation of their central effects. Recently, in man, vibration has been shown to produce interesting motor effects when applied to a muscle contracting voluntarily[7].

Reversibility of an Electrical Correlate to the Process of Learning

The cockroach normally holds a chemically stimulated antenna with the opposite fore-leg during the process of cleaning. Immediately after the amputation of both fore-legs the insect is unable to hold its antennae with one of the middle legs. This, however, the cockroach can do about one week after operation.

In previous communications it was concluded that a cockroach with amputated fore-legs must learn to stand on three of the remaining legs when holding the antenna with one middle leg. It was also demonstrated that a nervous pathway impermeable to a single pre-synaptic stimulus (in 90 per cent of normal adult cockroaches) becomes permeable to this stimulus in all the insects at a certain moment during the process of learning[1,2]. The preparation investigated consists of a descending pathway from the oesophageal ganglion to one of the motor nerves of the hind leg. This pathway has synaptic connexions in the third thoracic ganglion.

The electrical response observed in 10 per cent of the cockroaches considered normal in a preceding communication[2] presented the characteristics of labile response, as described by Luco[3]. It shows a long and variable ganglionic delay (4·10 msec ± 0·232 *S.E.*, ref. 2). During learning, about the seventh day after amputation of the fore-legs, the response in all the insects was characteristic of a servile response[3]. It presented a short and constant delay (1·93 msec ± 0·078 *S.E.*, ref. 2). The pathway remained open so long as the learned reaction was being used, that is, as long as reinforcement was acting. In previous experiments this process was followed up to the fiftieth day after amputation.

The present communication deals with the reversibility of the modifications of responsiveness of this nervous pathway to single stimuli while the learned action is no longer performed, because newly formed fore-legs were used to grab the antennae. This situation was achieved by amputating both fore-legs in a series of 26 cockroaches during the period of moulting. Young cockroaches were operated on and after three to four moults the regrown forelegs were strong enough to hold the antenna for cleaning. From 15 to 20 days after this stage was reached, the two new fore-legs were amputated and both the behaviour and the electrical response of this nervous pathway were investigated using the previously described

technique[2]. This situation implies that for a period of about 20 days the insects were not using the middle legs for holding the antenna, which may be interpreted as a lack of reinforcement for about three weeks.

Twenty-one of the 26 cockroaches were able to use one of the middle legs for holding the antenna immediately after the amputation of the two regrown fore-legs. The remaining insects made unsuccessful efforts to grab the antenna during the first hours after operation, but within the first day they could use one of the middle legs. An improvement of the behavioural performance was evident through the first two post-operative days.

The electrical activity was studied *in vitro* immediately after operation and for a period of up to six days. Fig. 1 shows the change of the synaptic delay values and their standard errors through the whole period of the experiment. It will be noticed that, at the beginning, a labile response was present, that is, the synaptic values were long and variable. Four days after, these values corresponded to those described as characteristics of a servile response. As can be seen in Fig. 1, the decrease of the mean synaptic values is faster than the decrease of the dispersion of these values.

In the previous work[2] the process of learning was considered to be related to a change in the permeability of synaptic transmission. When the synapse was closed (90 per cent of normal adult insects), it opened during learning; this opening meant a servile response. If the labile response was present before learning (10 per cent of the cockroaches considered normal), it also became a servile response after learning.

As described in this communication, the labile response is always present in the group of cockroaches that had already learned the new motor behaviour and which for about 20 days had not performed the acquired motor reaction. The labile response can be interpreted as a trace of a learned behaviour that lasts for at least 20 days, during which there is no reinforcement.

From the results described here it is pertinent to suggest that whenever a labile response could be elicited by a single presynaptic volley, the nervous system had already reached a physiological condition that enabled the cockroach to use one of the middle legs for holding the antenna.

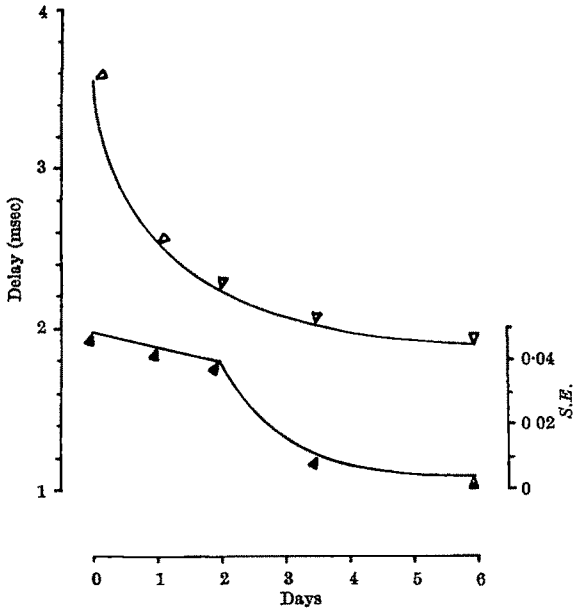

Fig. 1. Ganglionic delay[1,2] of an all or none response (*in vitro*) in a motor axon of the third thoracic ganglion and its standard error. A single electrical stimulus was applied between the œsophageal ganglion and the first thoracic ganglion. Abscissa, days after amputation of both regrown fore-legs. Ordinate on the left, delay in msec, △; ordinate on the right, standard error in msec, ▲. Each point represents the mean value of 300 measurements. The value *P* between two adjacent delay points (△) is less than 0 001

It can also be suggested that the transformation of a labile into a servile response represented an improvement of the system resulting in a better adjustment of the motor reaction.

On the other hand, it could be concluded that a 20-day period of disuse of the learned reaction produced a partial loss of the behavioural ability. This effect can be called the 'forgetting-process' and can be correlated to a change of a servile response into a labile one. Conversely, 3–4 days of reinforcement enable these cockroaches to achieve the highest behavioural efficiency. This 'relearning process' seems to be related to the transformation of a labile response into a servile one.

It is worth while emphasizing that the change of synaptic permeability appears as a smoothly graded process from a closed to an open synaptic transmission. Three situations have been considered to be operationally useful: (1) the lack of response; (2) the typically labile response; (3) the typically servile response. The lack of response may be interpreted as a response with a very prolonged delay; should this delay be shortened, a labile response may appear and, in case it reaches the shortest value, a servile response appears. Besides, the fact that the dispersion of the synaptic delay value is decreasing during the process of learning is another reason for suggesting that a graded transmitter efficiency is being built at the synapses during learning.

It has also been demonstrated[2,4] that a modification of permeability of this motor pathway can be achieved acutely by a short tetanic stimulation; but it lasts only for a short period. Should no response be present before a tetanic stimulation, a labile response may appear after the tetanus. When a labile response is recorded before a tetanus, the latter may change this labile response into a servile one. The main difference between the process achieved acutely and the process achieved during learning is that in the former case both building-up and decay of the process occur more rapidly.

Fraction of the Motoneurone Pool activated in the Monosynaptic *H*-Reflexes in Man

The monosynaptic reflex response evoked in the cat by a maximal volley in the group I*a* afferent fibres from a synergic group of muscles has been measured as a fraction of total motoneurone pool of that muscle by Jefferson and Benson[1] and found to range between 4·3 and 26·5 per cent. Apparently there has been no measurement of the activated fraction of the motoneurone pool with the analogous *H*-reflexes that are evoked in the gastrocnemius-soleus muscle of man by stimulation of the group I*a* fibres in the popliteal nerve[2–4].

In the present series of experiments the popliteal nerve was stimulated by an electrode carefully placed on the skin overlying it in the popliteal fossa and the electrical responses were recorded from the soleus muscle by two surface electrodes. Both electrodes mounted in one rubber strip were located and cemented to the skin on the upper third of soleus muscle. In this way it was possible to avoid any shift of recording electrodes by muscle movement. Suitable earthed leads minimized artefacts, and the electrical responses were amplified and photographed in the conventional manner.

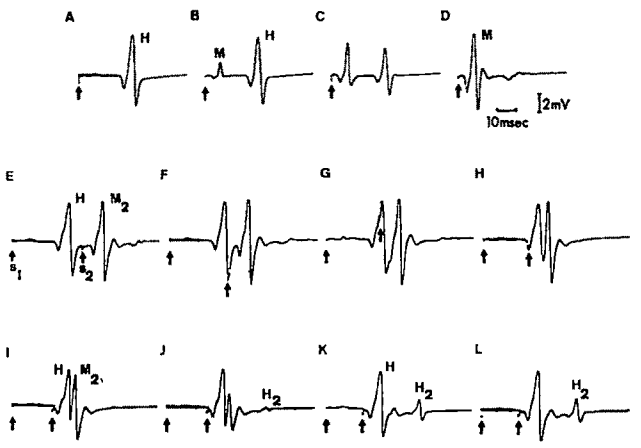

Fig. 1. Electrical response of m. triceps surae after electrical stimulation of N. tibialis post. *A*—*D*, Stimulation with increasing stimulation intensity. The progressive decrease of the amplitude of the *H*-reflex is shown. In *D* it can be seen that the strongest stimulation caused complete blockade of the *H*-reflex. *E*–*L*, Double stimulation. *I* shows the second *M*-response superposed on the latter part of the *H*-response. In *J*–*L* progressive increase of the H_2-response was evoked by the second stimulus. Time, 10 msec; amplitude, 2 mV

Presumptive evidence for activation of a large fraction of the motoneurone pool has been obtained in several subjects (5), in which the responses to graded intensities of stimulation gave a series such as that illustrated in Fig. 1*A*–*D*. The weakest stimulation evoked a large triphasic muscle action potential (the *H*-reflex) with a latency of 32 msec. With progressive stimulus increase (*B*, *C*) this spike declined as a much earlier triphasic spike developed. It is well known that this is due to direct stimulation of the motor nerve fibres to the gastrocnemius-soleus muscle, which have a higher threshold to electrical stimulation than the group I*a* afferent fibres[2–6]. Besides causing the early muscle action potential (the *M* response) with a latency of about 8 msec, the impulses generated in these motor fibres pass antidromically to the spinal cord and cause a blockade of the monosynaptic reflex discharge (the *H*-reflex) either by collision with this impulse discharge or by the refractoriness that the antidromic invasion induces in the motoneurones.

As shown in Fig. 1*D*, the strongest stimulation caused this blockade of the *H*-reflex to be virtually complete. The *M*-spike response produced in these circumstances can therefore be assumed to be due to activation of almost 100 per cent of the motor axons of the gastrocnemius-soleus muscle, and hence of the motor units of this muscle. The largest action potential of the *H*-reflex in Fig. 1*A* is a little smaller in size than the maximum *M*-spike of *D*. However, close inspection reveals that the triphasic *H*-reflex potential is composed of a more asynchronous response of the motor units, the interval between the initial and terminal positive waves being 6 msec as compared with 5 msec for the *M*-spike. This asynchronism can, of course, be attributed to the much longer neural conduction pathway for the *H*-reflex with the interpolation of a synaptic relay. It seems likely that the increased asynchronism of the constituent motor unit responses is sufficient to account for the smaller size of the *H*-reflex spike relative to the *M*-spike in Fig. 1*E*. Similar evidence for a virtually total activation of the motoneuronal pool has been obtained in several other subjects.

A crucial test of this presumed total activation is illustrated in Fig. 1*E*–*L*, the control *H* and *M* responses being in Fig. 1*A*, *D*. A maximal *H*-reflex was set up by a stimulus that was just at threshold for the most excitable motor axons, as may be seen by the extremely small initial *M*-spike. The testing stimulus evoked an almost maximal *M*-spike, as is demonstrated by the very small *H*-reflex that followed the *M*-spike. With progressive shortening of the interval by which the testing *M*-spike followed the *H*-response it is seen that there was no appreciable change in the *M*-spike until it was superposed on the latter part of the *H*-responses (*I*). Further advance of the testing *M*-spike stimulus then resulted in a rapid decrease of the *M*-spike and, in the last record of the series (*L*), the spike induced by the combined stimulation could be exactly superimposed on the control *H*-reflex response (the first response of *E*). Thus it is established that, within the limits of accuracy of this experiment, the *H*-reflex in Fig. 1*E* was occurring from 100 per cent of the motoneuronal pool. It will be noted in *J*–*L* that there was a progressive increase in the *H*-response (H_2) evoked by the second stimulus. This is, of course, to be expected, as refractoriness prevents the second stimulus from exciting the motor axons and so blockading the *H*-reflex as already described.

A similar result was obtained in another subject in which the *H*-reflex was almost as large as the *M*-spike. In that subject comparison of the *H*-reflex and *M*-spike sizes also indicated activation of virtually 100 per cent of the motoneurone pool by an *H*-reflex. However, there are many subjects in which a much lower activation —even less than 50 per cent—is indicated by the comparison of the *H*-reflexes and maximum *M*-spikes. The measurement of the motoneuronal fraction involved in *H*-reflexes should be a standard procedure in all investigations in *H*-reflexes. For example, in testing the effect of muscle stretch on *H*-reflex it was sometimes found that there was almost no change in sizes of the reflexes. This stability of the *H*-reflex, under conditions of presumed inhibitory or facilitatory influences, would be expected if motoneurones were so powerfully excited that all of them were supramaximally excited in the *H*-reflex.

PHARMACOLOGY

Blocking of Cortical Inhibitory Synapses by Intravenous Lidocaine

It has been shown by various pharmacodynamic examinations that systemically administered local anaesthetics act only depressively on the central nervous functions: for example, the cortical after-discharge[1], the spinal reflex[2], the reticular activating system[3], the thalamic activating system[4], the direct cortical response[5], and the transcallosal evoked potential[6]. The reason why local anaesthetics in a toxic dose manifest a central nervous excitation or convulsion has so far remained obscure.

We recorded extracellularly unit firings of a cortical neurone at the sensory-motor area in unanaesthetized rabbits immobilized with gallamine. In some neurones the transcallosal stimulation (0·5 msec, 100 c.s and 10–20 V for 1–3 sec) induced complete blocking of spontaneous firings (Fig. 1*A*). Intravenous injection of a small dose of lidocaine (7 mg/kg) abolished or attenuated the effect of stimulation (*B*–*E*), and perfect recovery followed it (*F*). In other neurones the transcallosal stimulation caused a marked increase in firings, and lidocaine injected in the same dose did not block this effect, whereas a large dose (15 mg/kg) partly inhibited the excitatory effect.

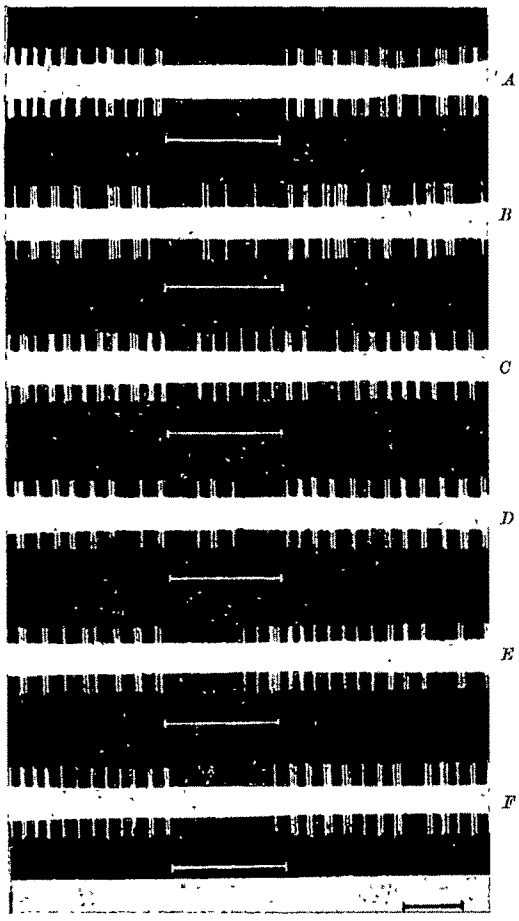

Fig 1. Effects of lidocaine on the inhibitory stimulation *A*, Control; *B*, 2 min, *C*, 4 min, *D*, 6 min; *E*, 8 min, *F*, 14 min after intravenous injection of lidocaine (7 mg/kg)

These results indicate that inhibitory synapses of cortical neurones are selectively blocked by lidocaine administered intravenously and excitatory synapses are more resistant to the drug. The mechanism of cortical excitatory action of local anaesthetics is thus interpreted, and the gap between behavioural observations and analytical experiments seems to be filled.

Enhanced Adenosine Inhibition of Platelet Aggregation in the Presence of Cardiac Glycosides

Blood platelets suspended in plasma readily exhibit aggregation when small amounts of adenosine diphosphate are added[1]. Aggregation can also be produced by the addition of 5-hydroxytryptamine[2,3] since this has been shown to release ADP from platelets[4]. Born *et al.* have shown that adenosine, its analogues or related substances, when added prior to an aggregating dose of ADP or 5-HT will inhibit the aggregation and may prevent it altogether[1,5,6].

It has been suggested[7,10] that adenosine is, at least partially, destroyed by adenosine deaminase in the plasma and hence the inhibition of ADP-induced platelet aggregation which it produces is of short duration and rarely lasts longer than 20 min. The 2-substituted chloro analogue, 2-chloroadenosine, is a far more potent and prolonged inhibitor of ADP-induced platelet aggregation[7] and is resistant to adenosine deaminase.

Both adenosine and 2-chloroadenosine produce heart block when injected into the left atrium of the guinea-pig heart and, whereas this effect of adenosine is brief and transient, that of 2-chloroadenosine is more powerful and very prolonged. The heart block produced by adenosine can be prolonged by the simultaneous administration of cardiac glycosides, and Angkapindu, Stafford and Thorp[8] have suggested that these drugs act as adenosine deaminase inhibitors.

We have examined the effect of cardiac glycosides on platelet aggregation following substantially the same method as Born[1,5] using sheep platelet/plasma suspensions. The cuvette containing the plasma mixture was in a temperature-controlled chamber and stirring was very precisely controlled. The turbidity changes were recorded as percentage light transmission using a continuous potentiometric recorder.

Sufficient platelet-rich plasma was prepared at the commencement of each day to allow comparison to be made between adenosine inhibition alone at various time intervals after addition and similar experiments which included the cardiac glycosides added prior to adenosine.. All experiments on any one day were performed on the same batch of plasma and comparisons have only been made between results obtained in such an experimental series since the aggregation response varies from one platelet/plasma batch to another.

The concentration of platelets was checked by direct count and was usually within the range $1{\cdot}0 \times 10^6$ platelets per cu. mm. As the aggregating agent either ADP or 5-HT was used and similar results were obtained in both cases.

Fig. 1*a* shows a comparison between experiments in which 5-HT was used to cause aggregation in the presence and absence of ouabain.

It will be seen that this control response is the same whether ouabain is present or absent, and other experiments have shown that this glycoside alone has no influence on ADP- or 5-HT-induced aggregation of platelets. Fig. 1*b* shows the results obtained when adenosine is added 2

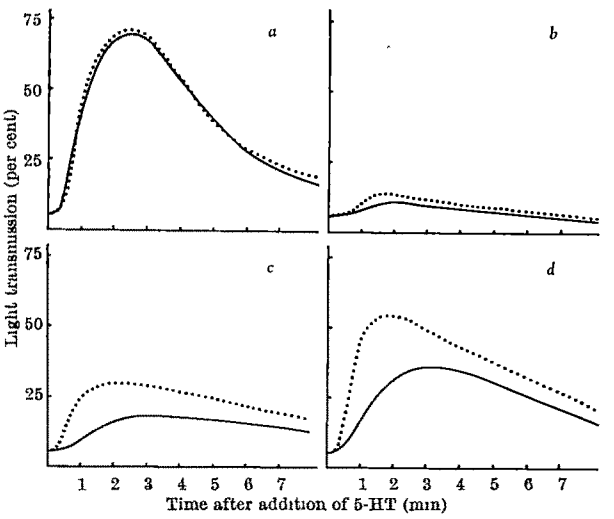

Fig 1. Aggregation curves for 5-HT (1·5 μM) added to platelet suspensions in plasma. *a*, Control responses; *b*, adenosine added (1·25 μM) 2 min prior to 5-HT; *c*, adenosine added (1·25 μM) 5 min prior to 5-HT; *d*, adenosine added (1·25 μM) 15 min prior to 5-HT. Responses (——) in presence of ouabain (100 μM); responses (.....) in absence of ouabain

Table 1. Percentage Inhibition of Platelet Aggregation when Cardiac Glycosides are added at Various Intervals of Time prior to 5-HT or ADP

Aggregating agent	Drug combination	Time interval (min) 2	5	10	15
5-HT (1·5 μM)	Adenosine alone (1·25 μM)	88	60	33	10
	Adenosine + ouabain (50 μM)	87	73	50	36
	+ ouabain (100 μM)	98	90	75	69
	Adenosine + *K*-strophanthin (40 μM)	87	68	36	11
	+ *K*-strophanthin (80 μM)	88	70	40	14
	Adenosine + digoxin (10 μM)	86	65	34	12
ADP (1·4 μM)	Adenosine alone (1·25 μM)	76	52	25	8
	Adenosine + ouabain (50 μM)	78	65	47	29
	+ ouabain (100 μM)	81	72	55	42
	Adenosine + *K*-strophanthin (40 μM)	75	52	30	13
	+ *K*-strophanthin (80 μM)	79	61	46	30
	Adenosine + digoxin (10 μM)	77	56	29	20

min before the 5-HT. It produces strong inhibition of aggregation which is influenced by ouabain only slightly. When 5 min elapses (Fig. 1*c*) between the addition of adenosine and 5-HT it will be seen that the presence of ouabain has resulted in a substantially smaller degree of aggregation than when adenosine is used alone.

Fig. 1*d* shows the effect after an interval of 15 min when the preservation of the adenosine is even more pronounced.

This effect has been shown with other cardiac glycosides, digoxin, strophanthin *K* and lanatoside *C*, but ouabain is more readily water soluble than other cardiac glycosides and hence can be used in higher concentrations. Comparative results for ouabain, *K*-strophanthin and digoxin are given in Table 1.

The percentage inhibition is measured by the steepness of the slope of the aggregation curve during the first 0·5 min after addition of ADP or 5-HT. It will be seen that the inhibition of adenosine destruction is dose dependent but in the case of digoxin it was not possible to obtain a sufficiently high concentration in the cuvette to exhibit more than the response to a low dose.

It is not possible to use organic solvents since these interfere with the aggregation process and hence all glycosides were used as solutions in saline buffered to *p*H 7·4.

Under the conditions we have used the aggregation curves are highly reproducible and the adenosine inhibition in all these experiments is greater in the presence of cardiac glycosides.

Recent investigations in this department by Dean and Maguire[9] have shown that ouabain is a competitive inhibitor of purified cardiac adenosine deaminase, and these results indicate that the deaminase in plasma is also inhibited by these drugs.

HAEMATOLOGY

Role of ABO Erythrocyte Groups in Human Histocompatibility Reactions

The role of red blood cell group antigens in human histocompatibility has long been a matter of controversy[1–6]. It has recently been noted by Griffiths and Crikelair[7], and by Kuhns, Rapaport *et al.*[8], that a rise in anti-A and anti-B antibodies may occur following the exchange of skin homografts between blood group-incompatible subjects. This communication describes a series of experiments which provide suggestive evidence that erythrocyte group antigens may, on suitable immunization of recipients, play a significant part in conditioning the response of these subjects to first-set skin homografts.

In the course of a preliminary experiment, five volunteers (3 A Rh+, 1 B Rh+, and 1 O Rh+ subjects) received one intradermal injection of red cell membranes obtained from an A Rh− donor. Fifteen days later, the recipients were challenged with a skin homograft from the same donor and with a graft from another subject (who was O Rh+). The red cell membranes were prepared from whole blood collected in Fenwal bags through a cation-exchange resin chamber, which eliminated 90 per cent of the blood platelets. 100 ml. of a 6 per cent dextran (mol. wt. 200,000) were added to the blood, and the lowest portion of the red blood cell sediment was collected. This fraction was centrifuged three consecutive times, and each time the upper layer, containing a supernatant leucocyte layer, was removed. The remaining purified red blood cell preparation was haemolysed utilizing distilled water and the sodium monohydrogen phosphate method of Ponder. The final preparation did not contain any detectable leucocytes after several observations in counting chambers. Technique of graft application and criteria used for the determination of skin homograft rejection by gross and stereomicroscopic observations of the graft surfaces have already been described in detail[9–13].

None of the recipients of red cell membranes (sensitized in this experiment with a single intra-dermal injection) responded with accelerated rejection or white graft reactions. The two shortest skin homograft survival times in these recipients occurred, however, when skin homografts from a red blood cell group-incompatible A Rh− donor were applied to O Rh+ and B Rh+ recipients, respectively (Table 1).

Table 1. Response to Skin Homografts after Sensitization with One Intradermal Injection of Erythrocyte Membranes

Dosage of A-erythrocyte membranes injected	Blood group of recipients	First set skin homograft behaviour (days) grafts from (A−) donor	grafts from (O−) donor
$3·4 \times 10^9$	A+	16	14
$4·0 \times 10^9$	A+	10	10
$6·3 \times 10^9$	A+	17	17
$4·6 \times 10^9$	O+	9	17
$6·4 \times 10^9$	B+	9	10

Following this investigation, four recipients were sensitized with four consecutive weekly injections of $6·4–9 \times 10^9$ group A_2B Rh−. (An A_2B donor was selected to attenuate possible risks of intravenous injection of erythrocytes in the recipients.) The red cell preparations used to sensitize the recipients were obtained from defibrinated blood (thereby eliminating blood platelets in the final preparations). Leucocytes were removed by seven or eight successive sedimentations in dextran. No white cells were visible after several observations made in counting chambers. Two subjects were sensitized intradermally, and the other two received intravenous injections of erythrocytes. Eight days after the final injection, each recipient was challenged with six skin homografts obtained from donors other than the source of erythrocytes used to sensitize the recipients. Two of the skin homografts were obtained from donors of blood group A_1B; one graft was obtained from an A_2B donor, and three grafts were obtained from subjects of blood group O. The method of preparation of skin homografts, operative technique, and criteria for the determination of skin homograft rejection were as already noted[9–13]. Tables 2*A* and 2*B* outline the results of the experiment, and correlate them with the known blood group compatibilities existing between donors and recipients. A consistent difference in survival times was noted between the behaviour of ABO-compatible and ABO-incompatible skin homografts applied to these subjects. In the recipients of intradermal injections of AB erythrocytes (Table

2A), the skin homografts obtained from AB blood group donors which were applied to O Rh+ recipients were accorded a shorter survival time (mean survival time of 6·4 days) than grafts obtained from O donors applied to the same recipients (mean survival time of 11·1 days). The responses of subjects sensitized intravenously were even more pronounced (Table 2B). In these individuals, all homografts obtained from ABO blood group-incompatible donors were rejected in accelerated fashion. There were two white grafts, two mixed white graft reactions, and two accelerated rejection reactions (4–5-day rejection). All other grafts were accorded a longer survival time; however, four ABO blood group-compatible grafts have been rejected more rapidly on an average than after intradermal immunizations.

Results of this investigation indicate that the ABO blood group antigens may play a more important part in conditioning the response of human subjects to skin homografts than has been previously suspected. This observation is consistent with similar reports on the role of such antigens in histocompatibility reactions in other species[14–16]. It is also in accord with the description of alcohol-soluble ABO antigens in leucocytes, as well as in other tissues, and particularly in vascular endothelium and epidermis[17–20].

It is of interest that the homograft responses described in this communication occurred in the absence of significant rises of anti-A or anti-B antibody titres in the recipients. Only small rises in titres were noted after erythrocyte sensitization, and again after the application of skin homografts. Such antibodies were neutralized by soluble A and B substances, by heating to 70° C, or by treatment with mercaptoethanol. It would therefore appear that the accelerated and white graft rejection responses noted in the ABO-incompatible recipients sensitized with red blood cell antigens may have been associated with mechanisms other than humoral antibody, such as cellular immune factors, which have been previously shown to mediate homograft sensitivity in man[21]. The observed results also cannot be attributed to erythrocyte incompatibility systems other than ABO. Incompatibility for red cell group antigen D was only noted between one recipient and six donors of skin homografts in this investigation, and the homograft responses in this subject did not differ from those observed in the D-compatible subject immunized through the same route. With reference to the possible bearing of leucocyte or platelet incompatibility on the results obtained, the X^aX^b (ref. 22) or 4^a4^b (ref. 23) leucocyte groups, as well as the Ko^aKo^b platelet groups[24,25], were considered. The

recipients were selected in such a fashion as to avoid the possible bearing of incompatibilities in these systems on the responses of the subjects to skin homografts. Results of this study therefore appear to indicate that the question of the possible role of ABO antigens in conditioning the response of human recipients to tissue transplants deserves further investigation. Observations outlined in this communication may be of particular relevance to recent descriptions of rapid kidney homograft rejection in ABO-incompatible recipients. Of twelve renal transplants performed in such individuals, nine were accorded survival times of less than 30 days[26]; in some instances, graft cyanosis occurred almost immediately after completion of vascular anastomoses[27]. It may be of interest to re-evaluate these data in the light of experimental results described here—with particular reference to the possible bearing of repeated blood transfusions on the renal homograft reactions observed.

Interactions of ε-Aminocaproic Acid with the Thrombin Clotting and Fibrinolytic Systems

Several reversible inhibitors of plasmin have been found to protect the latter from irreversible combination with antiplasmin within appropriate limits of time and concentration parameters. However, ε-aminocaproic acid (EAC) and several related compounds appeared to potentiate the destruction of plasmin by antiplasmin, even though they were able to stabilize the enzyme against autodigestion in the absence of antiplasmin[1,2]. Because of the complexities of the two-phase model system used for these examinations, it was difficult to decide whether the results could be explained entirely on a kinetic basis, or whether in addition some unique reaction involving EAC and related structures could be taking place. The present investigations of a single-phase clot lysis system provided unexpectedly dramatic visual evidence in favour of the latter possibility.

Fibrinogen, thrombin, plasminogens, plasmins, trypsin and inhibitors were isolated or obtained as previously described[1-3]. Clots were made in tubes in initial experiments with 20 units of thrombin/ml. and usually 2 mg fibrinogen/ml., and observed at 25° C. During the course of a study of effects of various inhibitors on lysis time of these clots by plasmin, it was soon noticed that some clots containing EAC became strikingly opaque over a period of time. Normal clots made in the buffer used[4], which had a *p*H of 7·4 and ionic strength of 0·3, remained clear indefinitely. A quantitative picture of this phenomenon was obtained by making the clots in spectrophotometer cuvettes and following the increase in absorbance at 350 mμ (Fig. 1). Analogous results were obtained with the same fibrinolytic levels of Kline-type human plasmin of similar purity, or with euglobulin-type human plasmins of higher specific activities which had been fractionated in DEAE-cellulose. Opacity did not develop in clots containing EAC by itself or in the presence of plasminogens or urokinase separately, nor was the absorbance of fibrinogen solutions affected by the plasmin–EAC combination. Clots containing 2 μg trypsin/ml. and 0·2 M EAC also showed no opacity up to the time of lysis of about 2 h.

Other inhibitors tested over a range of levels which did not induce opacity with plasmin include Trasylol, Kunitz pancreatic trypsin inhibitor, and soybean and lima bean trypsin inhibitors. Furthermore, addition of sufficient levels of these inhibitors to clots containing plasmin–EAC prevented the usual opacity development. In fact, higher concentrations of EAC itself greatly delayed the time of initiation of opacity development, and this effect was not due to any significant change of *p*H or ionic strength of the medium, as determined by glass electrode and conductivity measurements. Several other inhibitors related to EAC, for example, lysine and γ-aminobutyric acid, also induced opacity.

At a given EAC level, the initial rate of opacity development depended on the concentration of fibrin or plasmin, while the maximum opacity was a function of the fibrinogen concentration. A quantitative kinetic analysis of these relationships is obviously complicated because lysis with consequent disappearance of opacity took place at a faster rate as the EAC : plasmin ratio decreased, and the initial rate of opacity development decreased at higher EAC concentrations.

These results suggest that there is an enzymatic activity associated with plasmin which results in structural

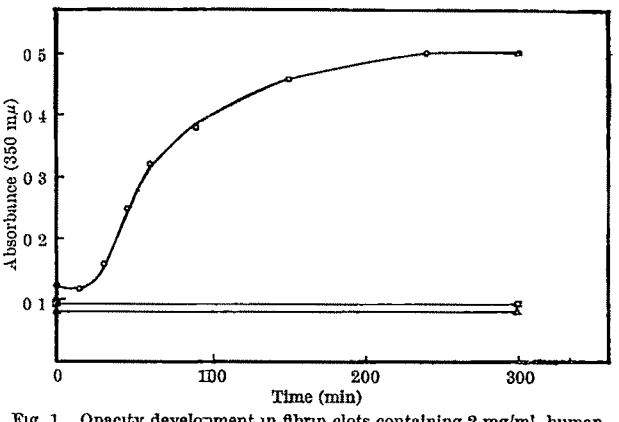

Fig. 1. Opacity development in fibrin clots containing 2 mg/ml. human fibrinogen and 20 units thrombin/ml. ○, Clot containing 70 μg/ml euglobulin-type human plasmin and 0·05 M EAC; □, clot containing 0·05 M EAC; ▲, clot with no additions

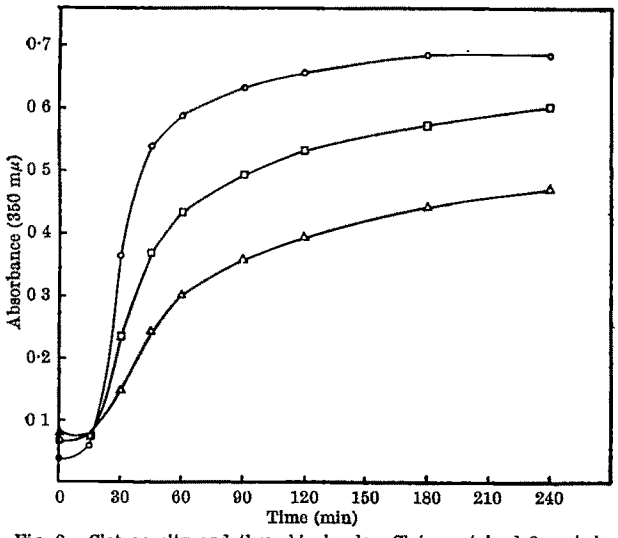

Fig. 2. Clot opacity and thrombin levels. Clots contained 2 mg/ml. human fibrinogen, 11 μg/ml. DEAE-purified human plasmin, 0·05 M EAC; and ○, 1 unit thrombin/ml.; □, 2 units thrombin/ml.; △, 5 units thrombin/ml.

modifications of the fibrin network in the presence of EAC and related compounds. This activity might involve a different site from the one concerned with fibrinolysis, since some other inhibitors of the latter do not induce opacity. However, since these inhibitors (as well as high levels of EAC itself) also prevent or retard opacity development with EAC, the possibility must be considered that the same site is involved and is catalysing some reaction which incorporates EAC into the clot structure, conceivably by amide bond formation; or there could be a limited hydrolysis taking place at bonds other than those split by thrombin, with large structural elements being aggregated by secondary forces. The structural implications of opacity in fibrin clots have been discussed by Ferry and Morrison[5].

When the thrombin concentration in the clots was reduced, additional complexities of the system were revealed and perhaps some insight as to mechanism was gained. As seen in Fig. 2, the development of opacity was inversely related to the thrombin concentration. In all experiments so far described, the order of addition of components was such that the fibrinogen was added last, which is our usual procedure in order to minimize fibrinogenolysis before the action of thrombin. It was now obvious that interaction of plasmin–EAC with fibrinogen sites had to be considered, by addition of thrombin after pre-incubation of fibrinogen, plasmin and EAC. The results of Fig. 3 strongly support the concept that the fibrinogen sites are indeed the susceptible ones. Further evidence that thrombin and plasmin–EAC are competing at the same sites is given in Table 1. Although plasmin–EAC significantly prolonged the clotting time, the resulting clots do not lyse for long periods of time; in fact, the seemingly paradoxical result was obtained that, in this range of thrombin concentration, the clots which formed more rapidly at the higher thrombin level were the first to lyse. This is understandable on the basis that the polymers resulting from thrombin action alone are more susceptible to plasmin hydrolysis.

Table 1. Effect of Plasmin and EAC on Thrombin Clotting Time*

Thrombin (units/ml.)	Plasmin (μg/ml.)	EAC (M)	Clot time (min)
1	—	—	13·5
2	—	—	5
5	—	—	2
1	—	0·05	15·5
2	—	0·05	8
5	—	0·05	2
1	11	0·05	30
2	11	0·05	11
5	11	0·05	3·5

* Plasmin and fibrinogen as in Fig. 2; fibrinogen was added last to these mixtures. With plasmin in the absence of EAC, clots did not form at any of these thrombin levels.

If pre-formed clots were made and plasmin and EAC added in a fluid supernatant, opacification could readily be seen developing at the interface and slowly spreading into the gel. Presumably, in any pre-formed clot structure, there are still sites available which have not been acted on by thrombin, and the latter is relatively immobilized in the meshwork of the gel.

Some information is available which allows speculation about the nature of the sites referred to here. At least with regard to action on synthetic substrates, the specificities of both thrombin and plasmin are directed toward arginyl and lysyl bonds; while the clotting action of thrombin is limited to arginyl bonds[6,7]. It might be postulated that plasmin action at arginyl sites is involved in the polymerization to a lysis-resistant structure in the presence of EAC, while concerted action at both arginyl and lysyl sites is required for hydrolysis. From structural considerations, it seems reasonable that EAC might interfere more at lysyl than at arginyl sites, and the experimental results are in harmony with this idea. Another implication of this hypothesis is that the plasmin autodigestive process would probably involve that part of the active centre related to lysyl bonds primarily. As the EAC concentration increases, interference at the arginyl sites does become evident, so that there is inhibition not only of lysis, but also of the reactions which lead to opacification. However, the arginyl sites acted on by thrombin alone must be differently situated, since EAC by itself has little effect on thrombin action.

It is obvious that there are additional complexities beyond this level of speculation. It appears that some reactions catalysed by thrombin are involved in the opacity phenomenon, and these reactions must be subsequent to the actions of plasmin (Fig. 3). Perhaps plasmin–EAC, while initially competing with thrombin (if present) for the latter's preferred sites, also by a limited hydrolysis in another area, exposes additional sites which can then be acted on by thrombin to produce the opaque, lysis-resistant structure.

Whatever the details may be, this interaction of EAC with the clot system only in the presence of plasmin makes it possible to understand better many previously puzzling

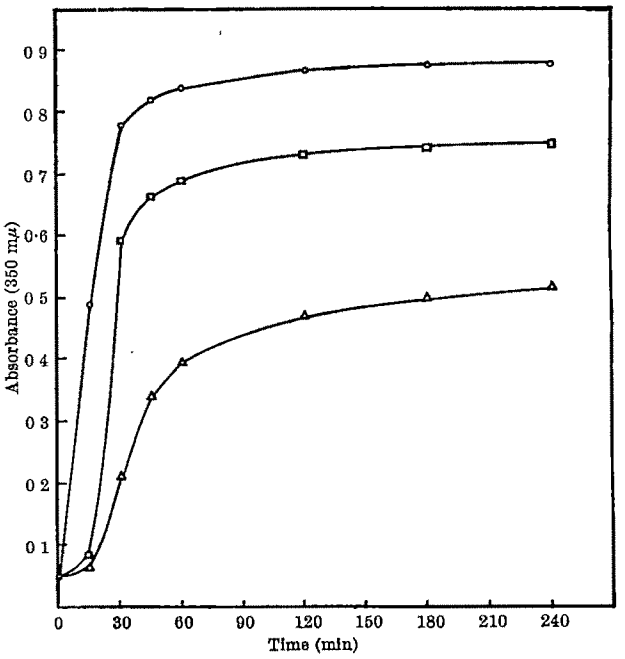

Fig. 3. Pre-incubation before thrombin addition. Clots contained fibrinogen, plasmin, and EAC as in Fig. 2; and 5 units thrombin/ml. added after pre-incubation of ○, 10 min; □, 5 min; △, 0 min

results in studies comparing EAC with other inhibitors, or comparing EAC inhibition of plasmin action on fibrin and on casein or synthetic substrates. For example, a more detailed interpretation is now possible for the increased destruction of plasmin by antiplasmin in the presence of EAC (refs. 1 and 2) if it is assumed that inhibition of fibrinolysis by EAC is largely due to interaction of EAC with the substrate rather than with plasmin. The EAC-modified clot is more resistant to lysis but the inhibition is reversible over a period of time. However, if an irreversible inhibitor such as antiplasmin is also present, it will remove free plasmin from the system before it can become effectively associated with the modified substrate. Whether or not a mechanism of this type should be called potentiated inhibition could be a matter of semantics or opinion, depending on whether one looks at the process or at the end result.

Additional interactions of EAC with the enzyme rather than with the substrate are, of course, not excluded. It can now be understood why EAC and other compounds which act by the same mechanism[2] may be stabilizers or enhancers of plasmin action at lower concentrations and inhibitors of fibrinolytic activity at higher concentrations, if in the former case interaction with the enzyme and inhibition of autodigestion are the more important effects, while in the latter case interaction with the substrate becomes sufficiently rapid or extensive to retard its digestion. Other reversible inhibitors which do not affect the fibrin substrate structure are able to insulate the plasmin from both autodigestion and antiplasmin for periods of time, during which fibrinolysis can take place[1,2]. With other substrates, casein, for example, much higher EAC levels in general are required for comparable inhibition, and this could be related in part to the fact that EAC does not interact with those substrates, or at least not in a way to inhibit their digestion by plasmin.

It is of interest that Donaldson[8] also suggested alteration of fibrin by EAC, on the basis of a decrease in urea solubility of clots containing EAC. While we have not been able to demonstrate this effect, such a result might depend on the type of fibrin used or other conditions of the experiments. The development of opacity described here might never be noticed if clots were made with preparations of fibrin which produce opaque clots originally, particularly at lower *p*H and lesser ionic strength; or if the thrombin : plasmin ratio were sufficiently high and the period of observation relatively short. It should be emphasized that the examinations reported here are concerned with interactions of human plasmin and human fibrinogen; our preliminary results with bovine plasmins and bovine fibrinogen indicate that the opacification phenomenon may not be readily observable with a bovine fibrinogen substrate. It is entirely possible that the largely physical changes leading to opacity may be mechanistically only indirectly related to the initial biochemical interactions which retard fibrinolysis.

Additional details and implications of these studies will be presented elsewhere.

We thank Violet S. Nickel for preparations of thrombin, fibrinogen, plasmins and antiplasmin.

PATHOLOGY

Renal Handling of Glycine in Primary Hyperuricaemia

The recent demonstration that patients with primary hyperuricaemia are also hyperaminoacidaemic[1] has suggested the possibility that the presumptive renal tubular defect in the handling of uric acid by these patients[2] may be only one manifestation of a more generalized transport defect that involves other substances. The amino-acid glycine, a purine precursor, has been investigated with the view of determining whether the elevated serum level of glycine can be explained on a renal basis.

Thirteen adult male subjects were investigated. Five patients were normouricaemic (mean serum uric acid of 5·3 mg per cent (4·3–6·0)) with a mean age of 35 years (22–55), a mean creatinine clearance of 108 ml./min (81–125) and a mean serum glycine of 260 μmoles/l. (224–285). Eight had primary hyperuricaemia (mean serum uric acid of 8·3 mg per cent (7·2–9·7)), with a mean age of 43 years (22–52), a mean creatinine clearance of 108 ml./min (82–132), and a mean serum glycine of 283 μmoles/l. (231–313). None of the subjects in either group was acutely ill, none had demonstrable hepatic or gastrointestinal disease or abnormalities of renal function, or was taking any drugs. The methods used were as previously described[1].

Endogenous glycine clearances were determined in the morning after an overnight fast and were based on a 2-h renal clearance. At the end of this 2-h period, glycine was fed orally in 2- or 5-g amounts, or administered intravenously in a dose of 0·9 g. 2 h later, another urine was collected to measure the increment in glycine excretion. Blood was drawn at 15, 30, 45, 60, 90 and 120 min after the glycine dose to determine serum glycine-levels at these times.

In Table 1, endogenous glycine clearances and glycine to creatinine ratios are shown. Both functions are lower in the hyperuricaemic individuals as compared with the normal subjects. The comparison of glycine excretion after the administration of a glycine load between the two groups is shown in Table 2. This comparison demonstrates that, regardless of the dose or route of administration, the hyperuricaemic subjects excrete less of the administered glycine.

Data from the serum investigations can be summarized as follows: (1) in the hyperuricaemic subjects the serum

Table 1. Endogenous Glycine Clearances and Glycine to Creatinine Clearance Ratios in Five Normouricaemic and Eight Hyperuricaemic Subjects

	77		1·4	53		0·3

level of glycine tends to reach a peak earlier than in the normouricaemic subjects; (2) the peak concentration of glycine tends to be slightly but not significantly lower than the peak concentration attained by the normal subjects; (3) there is no correlation in either group between the peak serum level and the quantity of the glycine load excreted in the urine ($r = \pm 0{\cdot}23$, $P = 0{\cdot}5$); (4) the disappearance of the administered glycine from the serum proceeds at approximately the same rate in both groups. Table 3 illustrates most of these phenomena.

Table 3 Serum Data after 5 g of Oral Glycine in Five Normouricaemic and Five Hyperuricaemic Subjects

	Normouricaemic	Hyperuricaemic
Peak serum level		
Reached at 30 min	1	5
at 45 min	4	0
Mean peak serum Level (μmoles/ml.)	1·56 (1·09–1·91)	1·27 (0·97–1·66)
Mean serum 'half-life' of glycine	33 min	31 min

The results of these investigations thus show that the kidneys of the hyperuricaemic individuals under-excrete glycine—a defect parallel to, and more marked than, the presumed defect in the excretion of uric acid by these patients. Such a result might have been expected from the known similarity of renal mechanisms for the handling of amino-acids and uric acid in dogs[3] and in kidney slices from various animals[4], from the fact that a uricosuric drug (salicylate) is also aminoaciduric[5], and from the observation that aminoaciduric syndromes are accompanied by uricosuria (for example, Wilson's disease and the Fanconi syndrome).

Whether or not the increased rate of net uptake of glycine by the renal tubular cell (either decreased secretion or increased reabsorption) occurs in other body cells as well cannot be definitively ascertained from the data presented. The earlier occurrence of the peak level of serum glycine concentration is suggestive of this, and the similarity of cell membrane transport systems in several types of cells[6] would lead one to expect that an abnormality in amino-acid transport across the renal tubular cell membrane might be duplicated in the membrane transport systems of other cells.

If such a universal cell membrane defect were the case, a unitarian hypothesis for the aetiology of primary hyperuricaemia suggests itself, namely, that primary hyperuricaemia is a disease of membrane transport. There is an increased rate of net uptake by renal tubular cells of at least one purine precursor (glycine) leading to decreased excretion, and increased rate of net uptake of purine precursor by purine-producing cells leading to increased availability of purine precursor within these cells and increased purine production. Thus the 'renal retention' and 'overproduction' theories of the aetiology of hyperuricaemia could be reconciled.

IMMUNOLOGY

Antigenicity of a Carboxymethylcellulose Bovine Serum Albumin Glycoprotein in Conventional and Germ-free Mice

During the course of studies on the biological properties of synthetic glycoproteins it seemed desirable to obtain information as to their antigenic properties. Micheel and co-workers showed that a number of compounds in which carbohydrate was covalently bound to protein were antigenic in their entirety when injected into rabbits[1,2]. Good antibody response to Pneumococcal Type III polysaccharide, the components[3] of which are structurally similar to those found in carboxymethylcellulose (CMC), has been shown in mice[4]. Since little is known with respect to the antibody response of germ-free animals in general and since mice are one of the easiest animal species to raise under germ-free conditions, it was hoped that this investigation would provide information with respect to the immunological responses of gnotobiotic mice in addition to the antigenic properties of CMC.

A synthetic glycoprotein containing CMC and bovine serum albumin (BSA) covalently bound to each other was administered to 14 Swiss mice which were housed in conventional quarters, and to 13 Swiss mice maintained in a germ-free environment in Fisher–Kewaunee–Horton units. The mice were approximately two months old when the injections were started.

The synthetic glycoprotein was prepared by adding crystalline BSA to a solution of CMC (mol. wt. 40,000) the carboxyl groups of which had been activated by 1-*cyclo*hexyl-3-(2-morpholinyl-(4)-ethyl)-carbodiimide metho-*p*-toluene sulphonate[5]. The linkages between CMC and BSA were of the amide type involving carboxyl groups of CMC and amino groups in BSA. The BSA not bound to CMC was removed by precipitation with $HClO_4$, with a final $HClO_4$ concentration of 20 per cent. The glycoprotein (BSA–CMC) was homogeneous when analysed electrophoretically in veronal buffer, *p*H 8·6, $\mu = 0{\cdot}1$, with a Tiselius-type model 38-*A* Perkin–Elmer electrophoresis apparatus equipped with a 6 ml. cell. The CMC/BSA ratio in the glycoprotein was 15. Full details of the preparation and properties of the glycoprotein will be presented elsewhere[6].

The glycoprotein (0·1 ml. of a 2 per cent solution using 0·85 per cent NaCl as the solvent) was administered to the mice via the tail vein twice weekly for a total of seven injections. Seven days after the final injection, the animals were bled retro-orbitally and killed. Serum was collected and its reactivity toward the following antigens was ascertained using the double-diffusion gel method[7]. The antigens were 2 per cent glycoprotein, 2 per cent BSA and 2 per cent CMC. Serum was also collected from four conventional and five germ-free mice to whom BSA had been administered and from four conventional and five germ-free mice to whom CMC had been given. BSA was administered in a manner similar to that described for the glycoprotein. An incomplete Freund adjuvant was used in conjunction with the CMC administration. The reactivity or BSA, CMC and glycoprotein to these sera was determined also by the double-diffusion gel method.

The reactivity of the synthetic glycoprotein antisera toward various antigens is summarized in Table 1. In both the conventional and germ-free animals, the glycoprotein was a potent antigen. In only one of the animals

Table 1. Immunological Response in Mice to Synthetic Glycoprotein and Reactivity of the Antisera to Various Antigens

Antigens	Glycoprotein antisera Conventional	Germ-free
2 per cent CMC	3/14	7/13
2 per cent BSA	12/14	12/13
2 per cent glycoprotein	13/14	12/13

in each group did the glycoprotein fail to elicit an immunological response detectable by the Ouchterlony procedure. The BSA and CMC moieties of the glycoprotein both served as antigens. Twelve of the 14 antisera obtained from conventional animals reacted with BSA and all but one of the germ-free animal antisera gave a positive reaction with BSA. Seven of the germ-free animal antisera precipitated in the presence of CMC whereas only three of the conventional animal antisera were positive in this respect.

Table 2. The Reactivity of Anti-BSA and Anti-CMC Sera to Various Antigens

Antigens	Anti-BSA sera	Anti-CMC sera
2 per cent CMC	0/9	2/9
2 per cent BSA	6/9	0/9
2 per cent glycoprotein	7/9	6/9

The reactivity of the anti-BSA and anti-CMC sera toward the three antigens employed in this examination is shown in Table 2. CMC gave a positive reaction with only two of the anti-CMC sera and BSA reacted positively with six of the nine anti-BSA sera. None of the anti-BSA sera reacted with CMC and no antibodies toward BSA could be detected in the anti-CMC sera. The synthetic glycoprotein formed precipitin bands with seven of the nine sera obtained from animals immunized with BSA and with six of the nine sera from mice injected with CMC.

The synthetic glycoprotein exhibited strong antigenic properties in both conventional and germ-free animals. Undoubtedly, the BSA moiety contributed greatly toward its antigenicity but the CMC portion also exerted some antigenic power, probably through a combination of factors, one of which may be the previously referred to structural similarity to Pneumococcal type III polysaccharide which has been shown to be a good antigen in mice[4]. Certainly the reactivity of the glycoprotein antisera with CMC is indicative of antigenicity of the polysaccharide moiety.

CMC did not appear to be a strong antigen, even when administered with the incomplete adjuvant. This may have been a result of the measuring device employed in this study since the anti-CMC sera, which gave only two positive reactions toward CMC, reacted to a greater extent with the glycoprotein, that is, six of the nine sera reacted positively with the glycoprotein. The apparent lack of antigenicity of CMC could be a function of its comparatively low molecular weight: 40,000. The minimum molecular weight of the glycoprotein as calculated from the ratio of the CMC and BSA content would be approximately 670,000. The compound of higher molecular weight should presumably be less subject to renal clearance.

The glycoprotein employed as an antigen in this examination was more resistant to attack by proteolytic enzymes, such as papain, than was the parent compound, BSA (ref. 5). This would indicate that the synthetic glycoprotein might retain its antigenic character longer than BSA. Wostmann has shown that BSA failed to elicit an immunological response in germ-free animals unless it was administered in conjunction with an adjuvant[8]. In our experiments, the synthetic glycoprotein was administered without any adjuvant being present and appeared to be a powerful antigen. This would indicate that the germ-free animal, when stimulated properly, is as capable of producing as good an immunological response as is the conventional animal. Bauer, Horowitz and Popper have shown that conventional and germ-free animals reacted in a similar manner when challenged by bacterial antigens[9].

Further examinations are in progress in which the antigenicity of CMC, BSA and glycoproteins of varying CMC/BSA ratios are being determined in germ-free animals.

BIOLOGY

A Comparison of the Calcium Concentration of Submaxillary Salivary Glands

This communication reports the calcium concentration of submaxillary salivary glands of mammals including man. The submaxillary glands of the rat have been reported to contain more calcium than blood or other soft tissue[1]. The calcium concentration of the submaxillary glands of other mammals have not been compared using the same analytical procedures. The work recorded here was undertaken to determine whether the high concentration of calcium encountered in the rat submaxillary gland was characteristic of these glands in other mammals and man.

Submaxillary salivary glands were removed from rats, mice, rabbits, cats, dogs and sheep, following lethal doses of sodium pentalbarbital. Cattle glands were obtained from an abattoir immediately after slaughter. Human material was obtained at autopsy by the Pathology Department of Ben Taub Hospital, Houston, Texas.

Whole glands or representative portions of the glands were dried at 100° C and ashed at 500° C for 24 h. The ash was dissolved in a small volume of 1 N hydrochloric acid and a sufficient volume of distilled water to obtain a final concentration of 0·1 N hydrochloric acid. Standards of known amounts of calcium were treated in the same manner. Calcium analysis was done on appropriate aliquots of the dissolved ash by automatic EDTA titration[2]. Calcium concentration was expressed as milligrams of calcium per 100 g of wet weight tissue. Repeated analysis of aliquots of the same ashed samples gave results within the limits of the precision of the method used[2]. Analysis of the right and left glands of three male adults of each species was used for the results presented in Table 1.

Variations in the calcium concentration of the glands from the same species were to be expected since the calcium content of this tissue is affected by the extent of salivation prior to death[3]. There is a marked difference in the submaxillary gland calcium concentration of the species examined as indicated in Table 1. Cattle glands have the highest concentration while those of mice are the lowest in calcium.

Table 1. The Calcium Concentration of Submaxillary Salivary Glands of Various Mammals expressed as mg of Total Calcium per 100 g of Wet Weight of Tissue

	Calcium content (average ± *S.E.* of mean)
Mouse (Swiss albino)	10·3 ± 1·6
Rabbit	15·2 ± 2·1
Human	18·1 ± 2·0
Rat (Holtzman)	30·1 ± 1·9
Sheep	49·1 ± 3·1
Cat	63·8 ± 4·8
Dog	70·1 ± 4·2
Cattle	84·0 ± 6·1

Histochemical examination of submaxillary glands shows differences between rats, rabbits, human beings, dogs and cattle[4]. The variation in the metachromatic properties used for their differentiation is apparently related to the sialic acid content of the mucins extracted from the glands[5]. A calcium-binding salivary gland mucoid, containing sialic acid, hexosamine and protein, has been isolated from bovine submaxillary glands[6]. On the basis of the calcium concentration of 3·3 per cent, this mucoid, which represents approximately 1 per cent of the wet weight of the gland, would account for more than 30 per cent of the total calcium present in the gland. There also appears to be a direct correlation between the calcium concentration of the salivary glands as reported in this paper and the published values of sialic acid concentration of extractable mucins of human, cattle, dog and rat glands[7].

This work shows that the calcium concentration of submaxillary glands is markedly different in the species examined. In mice it is as low as that found in plasma, whereas in cattle it is 7–9 times this value.

In view of the fact that a bovine salivary gland mucoid has been reported to contain a high amount of calcium and that the sialic acid content of the mucoid of four species is in the same order as the calcium content of the submaxillary glands found in this communication, it is suggested that the calcium content of salivary glands is related to the sialic acid content of the mucoid present.

Effect of *N*-Dimethyl Amino-succinamic Acid (*B*-995), a Growth Retardant, on Drought Tolerance

Recent information has shown that growth retardants such as (2-chloroethyl) trimethyl ammonium chloride (CCC) and 2,4-dichlorobenzyltributyl phosphonium chloride ('Phosfon'), applied as foliar sprays, can increase the drought tolerance of certain plants[1–3].

Another growth retardant, *N*-dimethyl amino-succinamic acid (*B*-995), has shown considerable promise as a retardant for fruit trees[4–6], but little information is available concerning its effects on drought tolerance. Greenhouse observations of growth reduction in several plant species indicated that *B*-995 may also increase tolerance to drought and this led to the work reported here.

In an initial experiment dealing with growth reduction in fruit trees, samples of fruit and leaves were taken from apple trees (variety 'Red Delicious') which had been treated with two sprays of 2,000 p.p.m. of *B*-995 six weeks earlier, and measurements of water deficit and transpiration rate were made. The water deficit of intact leaves was determined by obtaining their fresh weight, saturated weight after water absorption through the petiole for 24 h in a humid chamber at 100 per cent relative humidity, and oven-dry weight (70° C). Water deficit was calculated as the change in water content on saturation expressed as a percentage of water content at saturation. As shown in Table 1, leaves and fruit from treated trees had a lower water deficit than the controls. This occurred whether samples were taken from fruiting or non-fruiting spurs.

The leaves used to determine water deficit were also used for determination of transpiration rate. After the leaves had become fully turgid, they were removed from contact with water, exposed to uniform atmospheric drying conditions in the laboratory, and weighed after 30 min, and 1 and 6 h to determine transpiration rate. As shown in Table 1, the treated leaves lost water at a slightly lower rate than the controls. However, in subsequent tests using a leaf potometer in which water was supplied continuously to the leaf petiole and transpiration rate determined by weighing, it was found that in only 3 out of 10 trials (10 leaves/trial) had treated leaves transpired less and in the remaining trials there was no difference in rate of water loss from treated and control leaves.

A more detailed investigation was then initiated with sunflower (*Helianthus annuus*) as the test plant. Seedlings were grown in 5-in. plastic pots of silt loam soil until the primary leaves were completely expanded and then the seedlings were treated with three sprays of 2,000 p.p.m. at 5-day intervals. When a noticeable difference in size between treated and non-treated plants had developed, watering was discontinued and the plants were allowed to gradually dry out the soil in the pots. As the plants wilted, samples were taken periodically to determine plant water content, plant water deficit, and soil moisture content. Plant samples were obtained by cutting off the entire top (leaves plus stem) of each seedling at a point just below the primary leaves. Soil samples were obtained by unpotting the seedlings and taking approximately 200 g of soil.

The samples were taken at four stages of wilting, with an elapse of time between each stage. Both treated and check plants were selected at the same time as they appeared to dry out at the same rate. The plants were selected on a visual basis as follows: stage 1, slight wilting, all plants expected to recover after re-watering; stage 2, moderate wilting, most plants expected to recover; stage 3, severe wilting, approximately half the plants expected to recover; stage 4, very severe wilting, most plants not expected to recover. At each stage, half the plants were re-watered to compare the ability of treated and control plants to recover following wilting.

There was no dramatic effect of treatment on the moisture status of the plants or of the soil in the pots (Table 2). However, treated and control plants differed in their ability to recover turgidity and resume growth on re-watering. All plants recovered from wilting stages 1 and 2, and only 1 check died at stage 3. However, at stage 4 seven of ten checks died and only three of ten *B*-995 plants died. An attempt was made to determine the transpiration rate of individual leaves which had been placed with

* All values are averages for 10 plants.
† Percentage of dry weight

their petioles in water in a humid chanber (100 per cent relative humidity) and allowed to regain full turgor. Determination of transpiration rate of leaves at each stage was hampered, however, because the check leaves tended to re-wilt quickly when removed from the humid chamber. In fact, at stage 4, only 1 of ten check leaves regained turgor in the humid chamber, although 9 of ten *B*-995 leaves did.

In summary, it can be said that *B*-995 treatment does not appear to have a consistent effect on the magnitude of water deficit developed by plants subjected to drought or to delay the onset of wilting; however, the treatment does seem to enhance the ability of the plant to recover on watering after severe drought conditions.

Short-term Temperature and Light Conditions associated with Auxospore Formation in the Marine Centric Diatom *Coscinodiscus concinnus* W. Smith

THE periodic appearance of auxospores in a uni-algal culture of the marine centric diatom *Coscinodiscus concinnus* W. Smith (Holmes and Reimann[1]) made possible an investigation of the temperature and light conditions under which auxospore formation occurs. By using the cross-gradient apparatus of Jitts *et al.*[2] I was able to expose potential auxospore forming cultures to 64 different light and temperature combinations simultaneously. The cells were examined daily by removing the culture vessels from the gradient block and scanning the contents with an inverted microscope.

Altogether three different experiments were run, each lasting 6–7 days. Cultures were used in which no auxospores or male gametes were visible initially. The population density of the culture used was adjusted with sterile media (see following) to yield approximately 100–200 cells per ml.—a density that was optimal for viewing under the inverted microscope. The incident light and temperature ranges were the same in each experiment, namely, 0·003–0·5 Langlies per min and 9·0°–26·7° C, respectively. However, different light and dark periods were used. In the first experiment the organisms were illuminated for 16 h daily, in the second for 12 h daily and in the third for 8 h daily. Guillard's[3] *f* medium, diluted with an equal volume of 80 per cent sea water collected near shore off La Jolla, and modified to yield a final concentration of 150, 250 and 25 μg at. of silicon, nitrogen and phosphorus per litre, was used in the first and third experiments. In the second experiment the silicon, nitrogen and phosphorus concentrations were reduced to 0·25 of that given here. The results of these experiments are summarized in Fig. 1, which includes observations on the presence of free-swimming cells (believed to be male gametes) in the experimental cultures as well as on auxospore occurrence.

The observations (Fig. 1) show that colourless uniflagellate male gametes developed and were released from the parent cells over a wide temperature (9°–26·7° C) and light (0·003–0·50 Langlies per min) range. This range probably somewhat exceeds the tolerance of the species for growth since the cells held at the extremes of light and temperature appeared very unhealthy in each of the experiments. The photo-period also influenced the range of conditions under which the gametes developed and were released. In the first and second experiments (16 and 12 h of light daily, respectively) the range of conditions suitable for male gamete formation was considerably more restricted than in the case of the shortest photoperiod (third experiment—8 h of illumination daily), where gametes appeared over almost the entire range of experimental conditions. A difference in nutrient concentration (second experiment) seemed to have little effect on the range of conditions under which male gamete formation occurred. The male gametes appeared in maximum abundance a day or two before auxospore formation, although co-occurrences were sometimes observed. In this latter case the peak abundance had passed and only a few living gametes were observed together with the auxospores.

Auxospore (zygote ?) formation occurred over a much more limited range of temperature and light intensity and is markedly influenced by photoperiod (Fig. 1). The results of the first and second experiments were rather similar in that auxospores formed only between 0·05 and 0·04 Langlies per min (see Fig. 1) and, with one exception, only between 21·6° and 24·1° C. Under the 8 h of daily illumination, however, a considerably wider temperature and light range was conducive to auxospore formation, namely, between 16·1° and 24·1° C and between 0·02 and 0·50 langlies per min. Furthermore, the shortest photoperiod (Fig. 1) accelerated the formation of auxospores. These were observed within 38 h after placing the cells on this light–dark cycle, whereas in the other two experiments, periods of 76 or more hours elapsed before auxo-

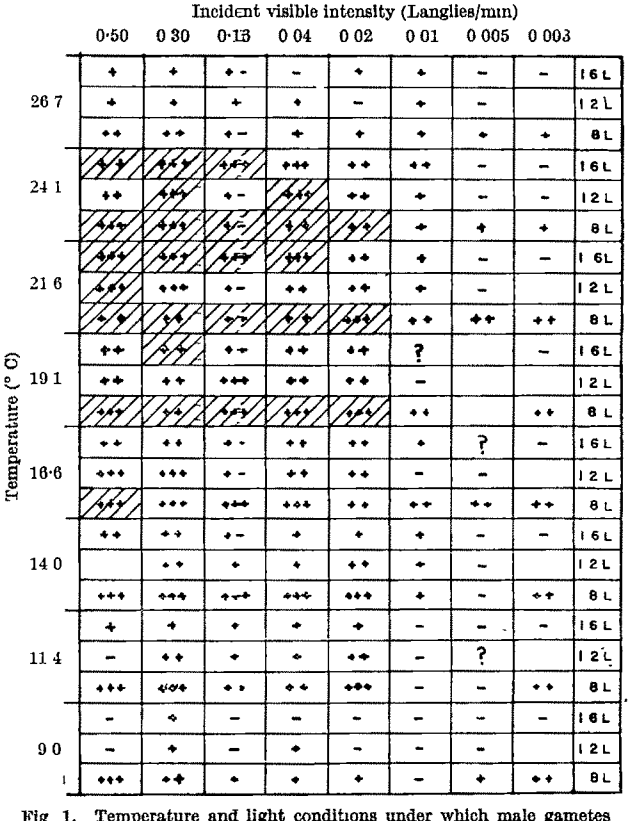

Fig 1. Temperature and light conditions under which male gametes and auxospores were observed in *Coscinodiscus concinnus* in three experiments with different photo-periods (16 light-8 dark, 12 light-12 dark, 8 light-16 dark, h daily). Male gametes, + + +, abundant; + +, common; +, rare; —, absent. The presence of auxospores is indicated by the hatched areas

spores formed. As was the case with male gamete formation, no appreciable effect of low nutrient concentrations (Exp. 2) was observed.

A number of factors have been reported to influence auxospore formation in centric diatoms[4–7] once the cells became physiologically capable of producing them[4,5,8]. Among these factors, light[4] and temperature[4,6] may be included. I know of no published investigation in which the effects of different photo-periods are discussed in this respect. Dr. Richard Norris of the University of Washington has informed me, however, that work carried out in his laboratory has revealed that short photo-periods will induce auxospore formation in *Ditylum brightwellii*.

An extrapolation of these experimental observations to the environment is perhaps premature, but the data suggest that in *C. concinnus* auxospore formation should occur near the sea surface where light intensity is high. Other things being equal, we would expect to observe this phenomenon under the broadest range of temperature and light during that portion of the year when the number of daylight hours is small.

This work was supported in full by the U.S. Atomic Energy Commission contract *AT*(11–1)–34, project 108.

Oxygen and Phytoplankton Changes in the Newly Forming Volta Lake in Ghana

The Volta Dam was closed on May 18, 1964, initiating the transformation of a tropical river into one of the largest man-made lakes in the world. This lake will lie between latitudes 6° N. and 9° N. along the 0° meridian. Stretching more than 250 miles, it will eventually cover an area of 3,275 square miles and hold 120 million ft./acre of water. The maximum elevation of the water surface will be maintained at 276 ft. above sea-level and the seasonal variation in depth will be 8–10 ft.

The plankton and the various physico-chemical factors of the water are being investigated by members of the Volta Basin Research Project of the University of Ghana[1]. An intensive investigation has been undertaken of samples collected at Ajena, 2 miles north of the dam site at Akosombo. At first, samples were collected from the surface in mid-stream and, shortly after the closing of the dam, the middle and bottom depths were sampled in addition by using a Ruttner sampler.

A correlation between the amount of dissolved oxygen and phytoplankton has been observed since the closing of the dam. Dissolved oxygen was estimated by Winkler's method and expressed as a percentage of the saturation according to Truesdale, Downing and Lowden[2]. Phytoplankton was estimated by the sedimentation technique, using an inverted microscope, and expressed as the number of individual organisms per ml.

Before closing the dam, the river water was supersaturated with oxygen (110–170 per cent saturation) irrespective of the density of phytoplankton. The dam was closed at a time when a waterbloom due to a blue-green alga, *Anabaena aphanizomenoides* Forti, was rapidly declining. The immediate effect was an abrupt increase of this alga accompanied by a phenomenal excess of dissolved oxygen of 324 per cent saturation; such an excess is rarely observed and the cause is not well understood[3]. In this case it appeared to be due to the increasing phytoplankton which contributed more oxygen to a suddenly stagnated water which was already supersaturated. Later, the rapid decline of *Anabaena* continued and the dissolved oxygen rapidly decreased to as low as 16 per cent saturation on June 19. An increase of phytoplankton then followed and another blue-green alga, *Microcystis flos-aquae* (Wittr.) Kirchn., succeeded, and formed a peak on July 10; at the same time the dissolved oxygen increased to 36 per cent saturation. The subsequent decline of *Microcystis* was found to correspond with the decreasing

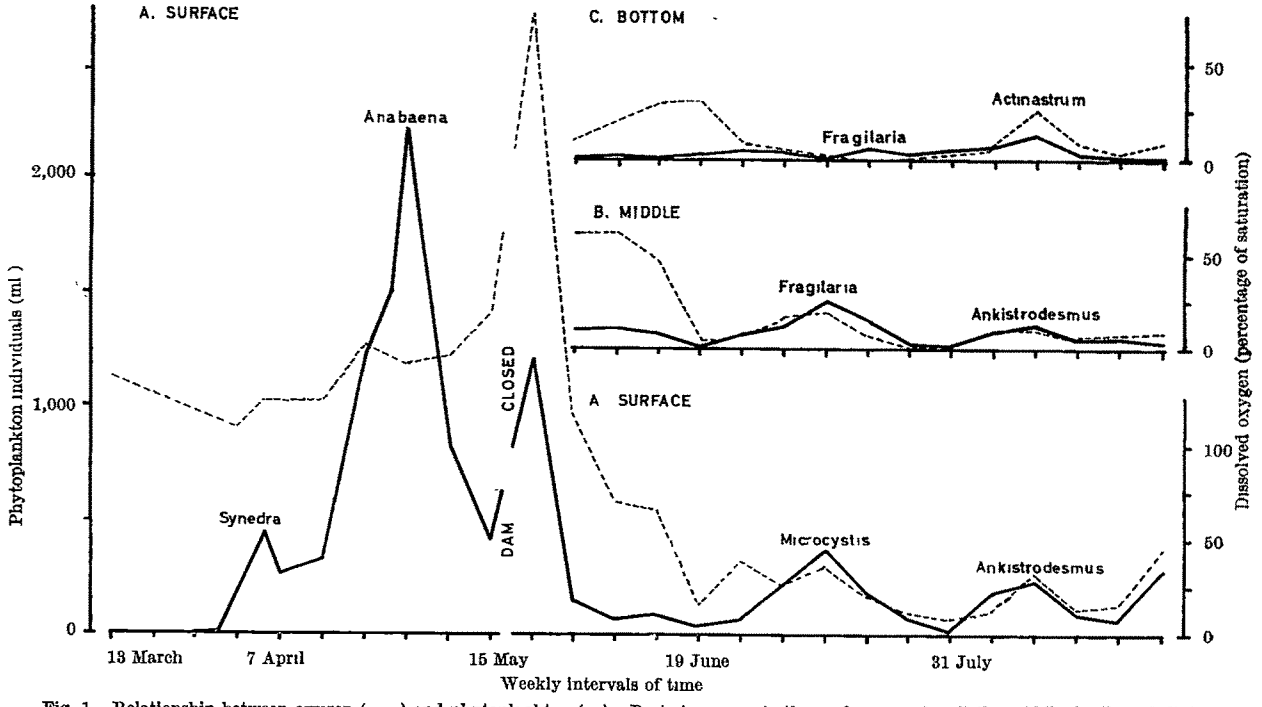

Fig. 1. Relationship between oxygen (- - -) and phytoplankton (—). Part *A* represents the surface samples, *B* the middle depth and *C* the bottom. The phytoplankton peaks have been labelled according to the dominant organisms of which they are composed

Table 1. Selected Data to show the Relationship between Oxygen and Phytoplankton Contents before and after Closing the Dam

oxygen content and by July 31 both were at their lowest. Later an increase of a green alga, *Ankistrodesmus falcatus* (Corda) Ralph., was associated with the increase of dissolved oxygen to 33 per cent saturation. It thus appears that the changes in the dissolved oxygen are intimately associated with the phytoplankton content. This is also true at the middle and bottom depths of the lake (Fig. 1, *B* and *C*).

The oxygen depletion was greatest on July 31 when the water was isothermal at 27·4° C through its depth of 24 m (≃ 79 ft.). So far there has been no establishment of permanent thermal stratification, as was also observed at Lake Kariba when its level was still rising[4].

I thank Prof. G. W. Lawson, Mr. R. S. A. Beauchamp, Prof. D. W. Ewer, and Dr. B. J. Harris, for their advice.

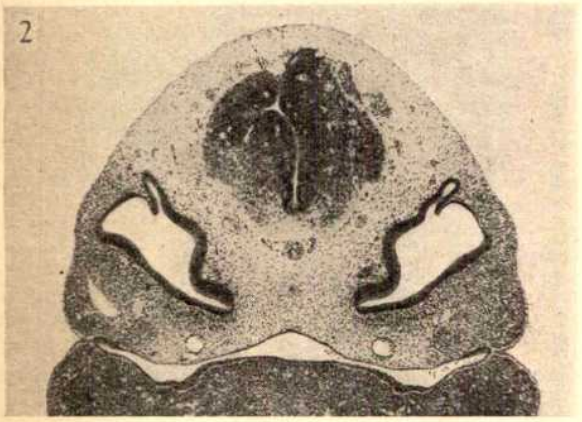
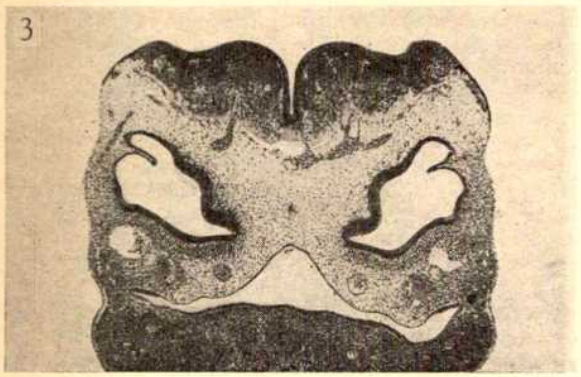
Influence of the Neural Tube on the Differentiation of the Inner Ear in the Mammalian Embryo



It has long been known from transplantation experiments that in amphibians and birds the differentiation of the otic vesicle into a normal labyrinth depends on the influence of the neural tube[1–4], but on account of the technical difficulties involved it has not been possible to extend these findings to mammals by means of similar experiments. The use of mutant mice is the most promising way of circumventing these difficulties. An analysis of the abnormalities of the inner ear in kreisler (*kr/kr*) mice[5] provided evidence that the neural tube plays the same part in the differentiation of the inner ear in mammals as in amphibians and birds. Confirmatory evidence was obtained from a study of dreher (*dr/dr*) mice[6]. It had been known for some time that, in this mutant, the differentiation of the inner ear was faulty. It was argued that, if the kreisler interpretation was correct, then in dreher embryos abnormalities of the neural tube in the region of the myelencephalon might precede those of the inner ear. This turned out to be the case[6]. Still further confirmatory evidence can be obtained by approaching the problems from the opposite direction, that is, by examining the inner ear in mutants where nothing is known about this organ but where the neural tube is known to be abnormal. Such an attempt is the subject of this report.



The mutants selected were Splotch (*Sp*)[7] and Loop-tail (*Lp*)[8]. The homozygotes in both these mutants have extensive abnormalities of the neural tube, and die during the middle or late stages of gestation. In *Lp/Lp* embryos, virtually the whole of the neural tube fails to close, and the neural tissue proliferates excessively. The abnormalities are similar in *Sp/Sp* embryos, but not so widespread, the neural tube often closing in the normal manner in the cervical and thoracic regions, and occasionally also in the cranial region. The material used was kindly supplied by Dr. Margaret C. Green and Dr. Margaret Dickie of the Jackson Laboratory, Bar Harbor, Maine, U.S.A., whose help is gratefully acknowledged. There were 27 embryos in all from the Splotch stock, 14 normal (+/+ or *Sp*/+) and 13 abnormal (*Sp/Sp*). Among the abnormals there were three in which the malformations of the neural tube were confined to the sacro-caudal region. Only 11 embryos were available from the Loop-tail stock, seven normal (+/+ or *Lp*/+) and four abnormal (*Lp/Lp*), but the results were so clear-cut that this number was considered quite sufficient. Since the differentiation of the otic vesicle does not begin until the 10-day stage and is complete in most essential respects by the 13-day stage, no younger or older embryos were examined.

The labyrinth was normal in the three *Sp/Sp* embryos in which the malformations of the neural tube did not extend to the cranial region. In all the other *Sp/Sp* embryos the differentiation of the otic vesicle was abnormal right from the beginning, although its position appeared to be normal. At the 10-day stage the point of origin of the endolymphatic duct is shifted backwards and upwards, and the duct itself is short and conical instead of being long and tubular. This difference becomes more pronounced at the 11-day stage, the duct growing backwards and outwards, and not vertically upwards as in the normal (Figs. 1 and 2). At the 12-day stage the cochlear tube can be seen growing in the medial direction. The vestibular part of the labyrinth now lies lateral to it, whereas its normal position is behind and above the cochlea. At the 13-day stage the vestibular part may even extend in front of the cochlea. Not a single structure in the labyrinth of *Sp/Sp* embryos is normal. The coiling of the cochlear tube is very poor, and the sacculus and the utriculus, in so far as they can be distinguished, bear little resemblance to the normal. The semicircular canals are present, but their planes, points of origin and relationship to the rest of the labyrinth are all abnormal. The anatomical situation is much the same in *Lp/Lp* embryos (Fig. 3), except that the abnormalities are even more severe: the endolymphatic sac in later stages grows to vast proportions, and the formation of the semicircular canals may be completely or partially suppressed.

In both the mutants the neural tube (or the neural plate) is believed to be the site of gene action. Its abnormalities appear before those of the inner ear. The latter cannot be explained away as the result of retardation or ascribed to mechanical causes. They may be regarded as secondary effects of the genes concerned, produced through the agency of the neural tube. This is evident from the normal structure of the labyrinth in the three *Sp/Sp* embryos in which the neural tube was normal in the cranial region. When considered in conjunction with previous work on kreisler[5] and dreher[6] mutants, the results of this investigation provide strong evidence that in mammals the differentiation of the inner ear is controlled by the neural tube in the same way as in amphibians and birds. Whether the neural tube exerts a direct influence or whether it works indirectly through its control of the movements and divisions of the facial-

Figs. 1–3. Transverse sections through the inner ear of an 11-day normal embryo (Fig. 1) (× 40), its *Sp*/*Sp* littermate (Fig. 2) (× *c.* 42) and an *Lp*/*Lp* embryo of the same age (Fig. 3) (× 40). Note that although the neural tube has failed to close in both *Sp*/*Sp* and *Lp*/*Lp* embryos, it is covered over by mesenchymous tissue in the former (Fig. 2)

acoustic ganglionic complex[5] is not clear. Mutants necessary for the elucidation of this point have recently been discovered, and their investigation is in progress.

ENTOMOLOGY

Plastron Respiration in Marine Insects

The immature stages of more than 150 species of insects appear to be restricted to the intertidal zone. Most of these are flies, and most of the flies belong to the families Chironomidae, Tipulidae, Dolichopodidae and Canaceidae. A fair number of beetles, a few bugs, and at least one caddis-fly also breed between tide marks. The immature stages of most of these insects absorb oxygen from the water directly through their cuticle. However, the respiratory horns of the pupae of apparently all Tipulidae, the species of *Aphrosylus* (Dolichopodidae), and *Canace nasica* Haliday (Canaceidae) are modified to form plastron-bearing spiracular gills. About thirty-five species of Canaceidae are known. All appear to be marine except two species of *Protocanace* that have invaded freshwater streams, one in the Hawaiian Islands and the other in Java. On general grounds I suspect that many of the pupae of the Canaceidae will be found to have plastron-bearing gills.

A plastron is a gas film of constant volume and an extensive water–air interface. Such films are held in position by a system of hydrofuge structures (Fig. 1) and can resist wetting by the hydrostatic pressures to which they are normally subjected in nature. In well-aerated water a plastron enables the insect to remain immersed indefinitely, when it obtains the oxygen it requires from the ambient water. Insects with a plastron are restricted to well-aerated waters because a plastron becomes a very efficient means of extracting oxygen from the tissues if the oxygen pressure of the environment falls below that of the tissues.

A characteristic feature of the environments that contain well-aerated water is that they may be alternately flooded and dry—streams, the littoral of lakes, and intertidal areas. The insects that inhabit them are therefore liable to be exposed above water. The great advantage of a plastron is that it enables the insect to meet the contradictory demands presented to it by such environments: a plastron is adapted both for the extraction of oxygen dissolved in the water and for atmospheric respiration. In water the plastron provides an enormous surface area for the extraction of oxygen, but, when the insect is exposed above water, it provides a direct route for the entry of atmospheric oxygen that does not necessarily involve water-loss over a large surface area because the connexion between the plastron and the internal tissues may be very restricted.

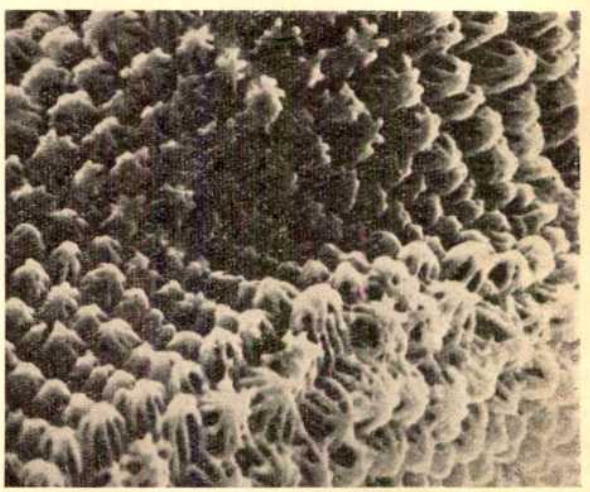

Fig. 1. Surface view of the plastron of the spiracular gill of *Geranomyia unicolor* Haliday taken with a stereoscan electron microscope

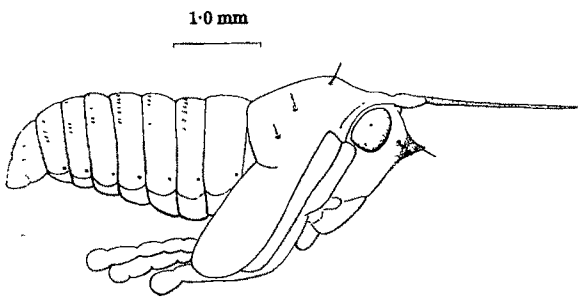

Fig. 2. Right side of the pupa of *Aphrosylus celtiber* Haliday. The plastron-bearing area of the spiracular gill is stippled

In most climates many terrestrial insects are alternately dry and flooded. When they are covered by water, the water is usually well aerated. To be submerged in water for several hours or even days when it rains heavily is no rare or isolated event but is a normal hazard of their environment. It might therefore be expected that many terrestrial insects are adapted for respiration in water in a manner no less complex than are many aquatic insects. Indeed, it has been shown that a wide variety of terrestrial eggs use the plastron method of respiration when they are flooded[1–6].

The intertidal Tipulidae all belong to the tribe Limoniini. It has previously been noted[7,8] that in all or nearly all Limoniini the epidermal cells which secreted the gill are left behind in the lumen of the gill at the time of the pupal–adult moult. During the pupal–adult moult a thin sheet of cuticle, the basal membrane, is secreted across the opening into the gill, with the result that the tissue in the gill is completely isolated from the haemocoele of the living animal not only by the basal membrane but also by a layer of moulting fluid and the cuticle of the adult. In *Geranomyia unicolor* Haliday, and presumably all other intertidal Limoniini, the epidermis that is shed at this time does not degenerate but remains in good condition throughout the pharate adult period, that is, from the pupal–adult moult to the pupal–adult ecdysis. It has been shown[7] that during this period the epidermis isolated in the gills of *Geranomyia unicolor* is competent to repair damage to the walls of the gill by secreting a plug of sclerotin.

In *Aphrosylus* epidermal cells are isolated in the spiracular gill in the same manner as in the Tipulidae. It may be noted here that epidermal cells are also isolated in the lumen of the respiratory horns of a number of terrestrial Dolichopodidae. The isolation of epidermal cells, or both epidermal and blood cells, in the spiracular gills or in the respiratory horns is now known to occur in about ten families of insects. Only a few of those insects which have evolved the habit of discarding tissue in the appendages of a previous stage exploit some of the attributes of the discarded tissue, which then comes to have a selective value it did not originally possess. The function of the isolated tissue in different spiracular gills has been summarized by me[8]: in some, for example the Simuliidae, it is used to expand the gill after the pupal–adult ecdysis[9], whereas in others it is used both to expand the gill and to maintain its turgidity throughout the life of the pharate adult, as in the Tipulid *Taphrophila vitripennis* Meig[7].

MICROBIOLOGY

Problem of Absolute and Relative Specificity of Intestinal Microfloras based on Investigations on *Bibio marci* (Diptera) Larvae

The question whether in the intestinal tract of arthropoda and worms, living in the soil and feeding on it, a specific microflora, differing from that of the soil, is existing or not has not yet been clarified. According to some authors the intestinal flora is essentially identical with that of the soil[1,2]. Others have found it different and characteristic of the animal species or group[3–5]. We examined this problem on streptomycetes living in the intestine of *Bibio marci* larvae. The larvae are extremely widespread in numerous soil-types of Middle Europe and live in populations containing 400 to 2,000 individuals (from the same egg-laying). Those examined by us were taken from a rendsina soil, where their food consisted of forest litter and the organic material of the soil. More than 500 larvae were dissected for the examination of the intestinal content, and the microbiological analysis of many excrement masses, which had accumulated under the larva-populations, was also carried out.

For the isolation of streptomycetes, glycerol–arginine[6], glucose–asparagine and glucose–casein agar-media were used. From the soil about 3,000 (ref. 7), and from the intestine and excrement more than 1,000 strains were isolated. The taxonomic examination of the strains was based on the internationally accepted methods of Shirling and Gottlieb[8]. The relationships of the great number of *Streptomyces* varieties, isolated from the intestine of the larvae, were tracked down by the use of the principles of numeric taxonomy, the determination of similarity indexes[9]. Isolates were determined on the basis of collective (parallel) examinations with type or authentic cultures of known species. The results can be summarized as follows:

(1) The percentage occurrence of streptomycetes in the total intestinal microflora of *Bibio marci* larvae fluctuated between 20 and 50 per cent. (2) While the number of *Streptomyces* and *Nocardia* species found in the soil was more than 30, the *Streptomyces*-flora of the intestinal tract was extraordinarily monotonous, only a few species being found, and absolute dominance of one or two species was characteristic. (3) In the intestine of individuals belonging to the same larva-population the species-composition of the *Streptomyces*-flora, more precisely the taxonomic identity of the dominant species (or several species), was the same. (4) Although it appears from point 2 that in the intestine a 'specific *Streptomyces*-flora' is formed, differing essentially from that of the soil, this specificity was not absolute, only relative. In the intestine of individuals of different larva-populations the same species did not consistently dominate. In other words, the local circumstances of the soil, the composition of food, etc., have an effect on the selecting processes taking place in the intestine, which in turn result always in the predominance of one or two species. (5) No *Streptomyces* species could be found which could live and propagate exclusively in the intestine. (6) The *Streptomyces* species found to be dominant in the intestinal tract showed remarkable variability and could be isolated in several varieties. (7) The *Streptomyces* species, dominating in the intestinal tract, preserved their predominance also in the fresh excrement of the animal, where one or two species may give 95 per cent of the *Streptomyces*-flora, and 70 per cent of the total microflora. These species are later gradually repressed, relinquishing their place to the natural multispecies microflora of the soil. (8) The most frequently occurring dominant *Streptomyces* species isolated from the intestine of *Bibio marci* larvae were the following: *Str. fimlayi*, *olivaceus*, *antibioticus*, *flaveolus*

and *aureofaciens*. A detailed account of this work will be published elsewhere.

VIROLOGY

Effect of 'Cephaloridine' on Vaccinia Virus *in vitro*

Experiments in our laboratory have indicated that a new cephalosporin preparation, 'Cephaloridine' (CR), is capable of arresting the development of a trachoma agent at an early stage, when used in concentrations as low as 0·1 μg/ml. of culture medium. In the present communication, some findings on the effect of this antibiotic on the multiplication of vaccinia virus in cell culture will be described.

A dermal strain of vaccinia virus (*V-Led-R*) was used[1]. Details of the preparation and storage of stock virus have been described elsewhere[2]. Cell cultures were prepared from a human kidney line originally obtained from the Laboratory of Hygiene, Department of National Health and Welfare, Ottawa, Canada. Growth medium consisted of *M* 199 containing 10 per cent calf serum. As maintenance medium, a 0·5 per cent solution of lact-albumin hydrolysate in Earle's solution supplemented with 2 per cent calf serum was used. Plaque titrations and experiments were carried out in Leighton tubes, in which confluent cell-sheets were obtained 2–3 days following inoculation with 1-ml. portions of growth medium containing 4×10^5 cells. Details of the plaque technique in liquid medium for the assay of virus and infected cells have already been reported[2,3].

In preliminary experiments, the effect of various concentrations of CR on plaque formation was examined. About 100 plaque-forming units (p.f.u.) of the virus were added simultaneously with the drug to cell cultures. As seen in Table 1, complete plaque suppression was obtained at a concentration of 500 μg/ml. A concentration of 300 μg/ml. reduced the plaque count to less than 50 per cent of that in controls, and the average plaque diameter by about 70 per cent. Plaque count and size in cultures treated with 50 μg/ml. were the same as in control cultures.

Control experiments indicated that a concentration of 1,000 μg/ml. of CR was toxic to cultures, causing the cells to slough off the glass. Since the dose causing complete plaque suppression was so close to the toxic dose, experiments were carried out to examine its effect on cells in the monolayer. It was found that exposure of cultures to 500 μg/ml. of the drug for 48 h had no damaging effect on the cells as judged by microscopic examination, uptake of neutral red, and growth on sub-culture. Moreover, following removal of the drug after 48 h, the cultures were as competent as unexposed controls in adsorbing and synthesizing virus, forming plaques of the same number and size and yielding the same amount of virus. All further experiments were therefore carried out with a CR concentration of 500 μg/ml.

Table 1. Effect of Various Concentrations of 'Cephaloridine' on the Development of Vaccinia Plaques in Cultures of a Human Kidney Cell Line*

'Cephaloridine' concentration (μg/ml.)	Average plaque No. experiments 1	2	3	Average plaque diam. (mm)
0	78	112	151	1·5
50	81	110	154	1·5
100	64	84	109	1·5
200	46	65	83	1·0
300	36	50	71	0·5
400	10	12	14	0·5
500	0	0	0	—

* CR was added simultaneously with virus, and the number of plaques and diameter were recorded after 48 h.

In order to determine whether the suppression of plaque formation was due to total or partial inhibition of virus multiplication, the increase in virus yield and infected cell count was determined in cultures treated with CR after they had been allowed to adsorb virus. As seen in Table 2, which summarizes a representative experiment, both values showed an increase in the CR-treated cultures which was, however, much smaller than that in the untreated controls. The virus yield after 24 h was only 1/50, and the infected cell count only a sixth of the corresponding values in control cultures. During the following 24 h, virus yield increased more than sixty-fold in the control, and less than two-fold in the treated cultures.

Table 2 Effect of 'Cephaloridine' on the Yield of Virus and Infected Cells in Cultures of a Human Kidney Cell Line*

Time (h)	Concentration of virus in p.f.u. per Control culture	CR-treated culture	Concentration of infected cells per Control culture	CR-treated culture
0	25	25	25	25
24	$1·2 \times 10^4$	$2·4 \times 10^2$	$1·2 \times 10^3$	2×10^2
48	$7·5 \times 10^5$	$3·5 \times 10^2$	ND†	ND

* Each culture was allowed to adsorb 25 p.f.u. of vaccinia virus, as determined from the average number of plaques in 3 control cultures inoculated at the same time and stained after 48 h. 500 μg CR were added to the appropriate cultures 2 h after the termination of a 1-h adsorption period.
† Not done.

A few experiments were carried out to examine the effect of the drug during various stages of virus-cell interaction. A reduction in plaque count of up to about 50 per cent was obtained when the drug was present during the adsorption period only. A similar reduction was noted when CR was incubated with the virus *in vitro* and the mixture was then diluted beyond an inhibitory drug concentration prior to inoculation into cultures. It seems, therefore, that a direct interaction between virus and drug can occur. In order to obtain information on the effect of the drug at different stages of the growth cycle of the virus, cultures were first inoculated at a multiplicity of 10–20 p.f.u. of virus per cell to ensure simultaneous infection of all the cells. After an adsorption period of 1 h, they were exposed to CR for various time intervals. As seen in Table 3, virus yields decreased with increasing periods of contact between drug and cells. No significant difference in yield was noted when treatment was confined to either the first or the last third of the 24-h period of the experiments.

Table 3. Effect of the Presence of 'Cephaloridine' for Various Time Intervals on the Multiplication of Vaccinia Virus in Cultures of a Human Kidney Cell Line*

'Cephaloridine' present (h)	Virus yield: control (per cent) Experiments 1	2	3
0–24	15	13	12
2–24	21	20	25
4–24	28	30	34
6–24	46	44	41
8–24	51	54	59
0– 8	67	65	68
16–24	74	70	71

* Control and CR-treated cultures were inoculated at a multiplicity of 10–20 p.f.u./cell, and virus yields were determined after 24 h.

On the basis of these findings, it would seem that there are two aspects to the action of CR. When it is present during the adsorption period only, it lowers the efficiency of the virus to adsorb to the cells or to penetrate and initiate infection. When it is added after the termination of the adsorption period, it causes a reduction in the amount of virus synthesized. As a result of this reduction, which does not seem to be related to a particular stage in

virus development, plaque formation is suppressed or impaired, depending on the drug concentration used.

'Cephaloridine' was kindly supplied by Glaxo Laboratories, Greenford, Middlesex.

PSYCHOLOGY

Behavioural Correlates of the Oestrous Cycle in the Rat

CHANGES in certain behavioural functions including learning and exploratory behaviour during the oestrous cycle of the intact rat have been reported[1,2]. Gray and Levine[3] recently re-opened the question of the extent to which sex differences in such essentially non-sexual behaviour could be determined by the altered behaviour of females during oestrus (heat). They induced oestrus in rats of the Maudsley reactive (*MR*) and non-reactive (*MNR*) strains by injections of oestrogen and progesterone and observed that emotionality as defined by emotional elimination and ambulatory activity in the open-field test was reduced. Our purpose is to repeat this work using natural as opposed to induced oestrus and to extend it both by the use of other inbred strains and measures of learning as well as emotionality.

The oestrous cycle was examined in 62 female rats, commencing at a mean age of 130·1 ± (*S.D.*) 31 days, in three highly inbred strains, *B*, *F* and *MNR* (*LAC* Nos. 163*b*, 163*c* and 163*g* respectively[4]), reared and maintained under carefully controlled and standardized conditions[5]. Mandl's technique[6] of daily vaginal smearing was used, though only four phases were distinguished: early oestrous, oestrous, early dioestrous and dioestrous. After an average of 37 days, 53 subjects which showed regular oestrous cycles were assigned at random to four groups representing the four phases distinguished, and each of these groups began behavioural testing in a different phase of the cycle as shown in Table 1. The lordosis response to manual stimulation of the vulvar region[7] was used throughout to confirm the presence of behavioural oestrus (heat) in rats showing an early oestrous smear.

Experiments were carried out in two phases. In the first, each subject was exposed in the open field[5] on five successive days to the mild stress of constant light (165 ft.-candles) and sound (78 dB above standard reference intensity) for precisely 2 min. Two scores were taken—the number of faecal boluses deposited, giving a measure of defaecation, and the number of compartments marked on the floor and traversed by the subject, giving, on conversion to a metric distance, the ambulation score. In the second phase, 12–36 days later, 44 subjects still showing regular cycles were given 40 trials each on a single day in a fully automated shuttle-box[8]. The rat learns to avoid an unconditioned stimulus shock of 0·2 m.amp by crossing to the other side during a conditioned stimulus (buzzer), the onset of which always preceded shock by 8 sec. The total number of these conditioned avoidance responses (*CAR*), their mean latency and the number of trials required to reach various criteria were all used as measures of learning. All testing was carried out in darkness after 9 p.m. (using red light for identification of subjects) in order to maximize the chances of detecting heat[9].

The results of both tests showed variation attributable to stage of oestrus. Open-field test results for a complete oestrous cycle were analysed separately for each strain because of the strain differences detected in defaecation and ambulation scores, which, incidentally, confirm those previously reported[10]. Because the *B* strain showed very regular four-day cycles, analysis of their ambulation scores was confined to the results for the first four days. The marked oestrual variation found throughout is shown in Table 1, in which the increment for rats in the early oestrous phase, irrespective of the day of its occurrence, is apparent. Analysis of variance of all scores grouped together for each stage, irrespective of day of testing, yielded a statistically significant *F*-ratio (5 per cent level). Subsequent *t*-tests showed that two of the three groups not in heat were significantly less active than the early oestrous group (mean score 6·00 ± 1·45 m). These were early dioestrous (3·93 ± 2·33) and dioestrous (3·84 ± 1·86). The results for the *F* strain were similar, though failing to show statistical significance, nevertheless supporting the view that heat facilitates ambulatory activity in the open field. The results for the third strain, the *MNR*, which had been tested 62·79 ± 5·31 days previously in the open field, suggested that this previous experience abolished both the oestral and daily variation in ambulation scores shown by the *B* strain (Table 1).

Table 1. MEAN AMBULATION (METRES RUN) ± *S.D.* IN OPEN FIELD ACCORDING TO PHASE OF OESTROUS CYCLE (*B* STRAIN)

Oestrous phase on test day 1	No. of subjects	Test day 1	2	3	4	Oestrous phase on test day 4
Oestrous	3	6·26 ± 2·06	1·66 ± 0·54	2·01 ± 1·81	*5·83 ± 1·63*	Early oestrous
Early Di-oestrous	5	6·82 ± 2·08	4·19 ± 1·71	*5·74 ± 1·47*	7·99 ± 2·81	Oestrous
Dioestrous	5	5·27 ± 0·78	*5·44 ± 1·38*	4·02 ± 0·76	2·72 ± 1·31	Early di-oestrous
Early oestrous	5	*6·95 ± 1·40*	3·76 ± 1·12	3·63 ± 0·11	3·15 ± 1·93	Dioes-trous
Total (all phases)	18	6·33 ± 1·63	3·99 ± 1·76	4·05 ± 1·72	4·82 ± 2·95	

Note: Results for groups tested when in early oestrous phase, irrespective of phase on test day 1, are in italics.

The defaecation scores for the *B* and *F* strains showed only a suggestion of a decrement during heat, in contrast with previous findings[3]. The *MNR* strain typically gave zero defaecation scores, having been negatively selected against this trait.

In the shuttle-box, rats of all strains in the early oestrous group consistently gave lower conditioned avoidance responses as compared with the other three groups. Analysis of variance for total number of *CAR*s out of the 40 possible yielded an *F*-ratio for oestrous stage significant at the 5 per cent level. The early oestrous group differed significantly (0·1–5 per cent by the *t*-test) from each of the other three groups. Mean *CAR* scores were 18·80 ± 3·98, for early oestrous group; 25·00 ± 5·97, for oestrous; 24·76 ± 4·77, early dioestrous; and 24·35 ± 5·49, dioestrous. The same significant differentiation of the early oestrous group from the other three groups was revealed in the avoidance latency scores (mean scores (sec): 3·61 ± 1·88, 2·60 ± 2·39, 2·99 ± 1·26, 2·92 ± 2·14 respectively). In addition, four criterial measures, based on the number of trials taken to achieve one, three, five and ten consecutive *CAR*s, lent supportive evidence. These results therefore indicate that during heat *CAR* acquisition was depressed.

It will be noted that the pattern we have detected during the early oestrous phase of the female rat's cycle is one of lowered indices of emotional responsiveness in the open field (increased ambulation and decreased defaecation) together with retarded acquisition of conditioned avoidance responses. This retardation has, however, been characteristically associated with greater emotional responsiveness in comparisons between the two Maudsley strains of rats[8]. On the other hand, the greater adrenal sensitivity to stress known to occur during oestrus[11] may well have occasioned less-efficient learning based on shock while still allowing expression of the gross activity differences which oestrus is known to occasion[2,12]. In the open field these might be seen in

greater ambulation and in the shuttle-box in greater pre-sessional and inter-trial activity—suggestions of which were in fact detected, and which may also have contributed to the poorer learning[13]. But the problem of the mechanism of the decrease in open-field defaecation, so clearly demonstrated by Gray and Levine[3], and which our results to some extent support, remains unresolved.

We thank the Medical Research Council for a studentship awarded to one of us (A. W. B.), and Prof. S. Levine for his advice. This investigation was in part supported by research grant *MH*-08712 from the National Institute of Mental Health, U.S. Public Health Service.

Locomotor Activity in *Drosophila* as a Function of Food Deprivation

Under conditions of constant temperature, *ad-libitum* food and a 12-h light–dark cycle locomotor activity in *Drosophila* follows a circadian rhythm with a peak of activity soon after light onset. Green[1], working with *Phormia regina*, has recently suggested that spontaneous locomotor activity is controlled by a hormone released from the corpus cardiacum. The release of this factor is thought to be under the control of receptors in the foregut capable of monitoring the presence or absence of food.

The present experiment was designed to investigate the effect of food deprivation on the rhythm of locomotor activity described here. Two groups, an experimental and a control, each containing five male and five female *Drosophila melanogaster* (Pacific strain), were used. Activity was measured in an open field apparatus which consisted essentially of a box made from white 'Perspex', 10 × 10 × 0·5 cm. In one side of the box was a small aperture fitted with a plug through which the flies could be introduced by tapping them from a funnel. The lid of the box, made from clear 'Perspex', was marked off into 1-cm squares. An activity score was obtained by counting the number of squares crossed by an animal in the course of a 5-min test period. All measurements were carried out at a constant temperature of 25° ± 1° C, in constant light conditions. The control group, on an *ad libitum* feeding schedule, were kept individually in vials containing yeasted agar-molasses media, while the experimental, food-deprived group were kept in vials containing cotton wool soaked in distilled water. Measurements were made every hour on each fly by tapping it into the apparatus, allowing 1 min for the animal to settle down and then measuring locomotor activity over 5 min. Measurements were made over an 8-h period from 1 h after onset of light. Fig. 1 shows the activity scores for the two groups. There is no significant change in the scores of the deprived group at the beginning of the experiment compared with their scores at the end, nor are the fluctuations significant. Initially there is no significant difference in activity between the two groups but after 7 h deprivation the difference is highly significant at $<0{\cdot}001$ level (t test). The control animals show a steady decline in activity; however, the deprived animals show no drop in activity and continue to perform around the peak of the circadian rhythm. If the control flies are taken as a baseline, it can be argued that in fact the activity of the deprived flies increases. Fig. 2 shows the percentage change in activity of the deprived animals as the experiment progresses. Flies in the experimental group spent increasingly less time preening as deprivation progressed; no such change was observed in the control animals. The effects of food deprivation in *Drosophila* appear to be similar to those found in rodents by Thompson[2] and Fehrer[3]. Experiments are in progress to investigate the genetic basis of spontaneous activity.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, January 10

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"Taurus and Tibesti" (colour films of recent expeditions).

SOCIETY OF CHEMICAL INDUSTRY, COLLOID AND SURFACE CHEMISTRY GROUP (joint meeting with the London Section of the Oil and Colour Chemists' Association, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mrs S. M. Rybicka and Mr. A. F. Sherwood. "Surface Properties of Titanium Dioxide Pigments".

Tuesday, January 11

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Alpha-Numeric Cathode-Ray-Tube Displays" opened by Mr. H. C. A. Hankins, Dr. A. T. Starr and Mr. L. W. Whittaker.

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. S. D. Sutton: "The Purpose and Nature of Management". 7 p.m.—Ir. O. K. F. Bussemaker (Netherlands): "Theory of Tack and Factors Influencing this Property".

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. T. L. H. Butterfield: "Design and Development of Fighting Tanks".

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Manson Theatre, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Discussion Meeting on "State Registration of Technicians".

PLASTICS INSTITUTE, LONDON SECTION (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Dr. D. E. Steele: "Plastics in Medicine".

Wednesday, January 12

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (at Imperial College, London, S.W.7), at 2.15 p.m.—Symposium on "Gains to Mathematics Teaching from a Decision to go Metric".

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (joint meeting with the Society for Applied Bacteriology, at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 2.15 p.m.—Meeting on "Microbiology of Desirable Food Flavours".

GEOLOGICAL SOCIETY OF LONDON (at the Shell Centre, London, S.E.1), at 5 p.m.—Prof. J. Tuzo Wilson: "On a Possible Explanation for the Crust's Growth and Movements" (Nineteenth William Smith Lecture).

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E.—I.E.E. MEDICAL ELECTRONICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Discussion on "The Analogue Computer and its Application in Medical Research" opened by Mr. B. Hammond, Mr. J. R. Abrahams and Mr. J. R. L. Read.

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMATIC CONTROL GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. P. K. M'Pherson, Mr. G. B. Collins, Mr. C. B. Guppy and Mr. A. Sumner: "Dynamics Analysis of a Nuclear Boiler".

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (at 17 Bloomsbury Square, London, W.C.1), at 6 p.m.—Dr. L. C. Payne: "The Impact of the Computer Age on Medicine".

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, Exhibition Road, London, S.W.7), at 6 p.m.—Dr. O. Bjorklund (Stockholm): "Principles Behind Standardized Shock and Bump Testing".

THE ASSOCIATION OF THE WILLIAM PENGELLY CAVE RESEARCH CENTRE, WITH IMPERIAL COLLEGE CAVING CLUB (in the Department of Physics, Imperial College, Prince Consort Road, London, S.W.7), at 7.30 p.m.—Dr. G. Warwick: "The Origins of Caves".

Wednesday, January 12—Thursday, January 13

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 9.30 a.m daily—Conference on "V.H.F. and U.H.F. Mobile Communications Systems and Equipment".

Thursday, January 13

MINERALOGICAL SOCIETY (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF CIVIL ENGINEERS, TRANSPORTATION ENGINEERING GROUP (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Liner Trains and Roundabout Trains" introduced by Mr. L. W. Ibbotson.

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Dr. W. Marshall: "Investigations of Magnetic Materials Using Neutron Scattering" (further lectures on January 20 and 27).*

CHEMICAL SOCIETY (in the Lecture Theatre, School of Pharmacy, Brunswick Square, London, W.C.1), at 6 p.m.—Prof. M. C. Whiting. "The Nature and Reactions of Classical Carbonium Ions" (Tilden Lecture).

INSTITUTION OF MECHANICAL ENGINEERS, STEAM PLANT GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Automation of Large Steam Plant".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Dr. F. P. Gloyns: "Problems Connected with the Use of Colour Film for Colour Television".

Friday, January 14

ASSOCIATION OF APPLIED BIOLOGISTS (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 10.50 a.m.—Symposium on "Damp Grain Storage".

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.), at 6 p.m.—Discussion on "How Should Engineering Education Take Account of Developments in New Materials?—Fibre Reinforced Materials".

Saturday, January 15

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Brian Moser and Mr. Donald Tayler: "Fiestas and Forests—Two Aspects of Colombia".*

Monday, January 17

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 2.30 p.m. and 5 p.m.—Colloquium on "Active Filters".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Prof. A. J. Birch: "Some Natural Anti-Fungal Agents".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. M. W. Thring: "The Present and Future Uses of Machinery". (First of three Cantor Lectures on "The Place of the Technologist in Modern Society".)

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Prof. M. G. Say: "Unusual Electrical Machines".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Major P. G. Boxall: "Island of Bliss".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TECHNICIAN (preferably with O.N.C. or equivalent in mechanical engineering, metallurgy or physics) IN THE DEPARTMENT OF PHYSICS, for work on the fabrication, maintenance and operation of crystal growing equipment—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (January 14).

COMPUTER OFFICER (with a suitable university degree and experience in computer programming and operation) at the Tidal Institute and Observatory—The Registrar, The University, Liverpool, quoting Ref. CV/375/N (January 15).

DEMONSTRATOR/SENIOR DEMONSTRATOR IN THE SCHOOL OF PHYSICS—The Registrar, The University Newcastle upon Tyne, 2 (January 15).

LECTURER IN HYDROLOGY IN THE DEPARTMENT OF FORESTRY AND NATURAL RESOURCES—The Secretary, The University, Edinburgh (January 15).

ASSISTANT LECTURER (preferably with special interests in electrophysiology or entomology and insect physiology) IN ZOOLOGY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (January 17).

RESEARCH ASSISTANT IN PHYSICS—The Registrar, University College of North Wales, Bangor, North Wales (January 20).

ASSISTANT LECTURER IN PSYCHOLOGY (any branch of the subject)—The Registrar, The University, Sheffield (January 21).

ASSISTANT LECTURER (with particular interest in experimental and applied psychology) IN PSYCHOLOGY—The Registrar, University College of Swansea, Singleton Park, Swansea (January 22).

LECTURER OR ASSISTANT LECTURER IN MATHEMATICAL STATISTICS, to work with an existing group of five members of staff—The Registrar, The University, Manchester, 13, quoting Ref. 229/65 (January 22).

LECTURER OR ASSISTANT LECTURER IN STATISTICS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Leeds, 2 (January 24).

LECTURER/SENIOR LECTURER IN VETERINARY VIROLOGY IN THE DEPARTMENT OF VETERINARY PATHOLOGY AND BACTERIOLOGY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 28).

ASSISTANT LECTURERS or LECTURERS (with interests in the following: statistics and operational research; pure mathematics, especially geometry and algebra; applied mathematics, especially discrete and numerical systems; mathematical physics, especially nuclear and elementary particle theory) IN THE DEPARTMENT OF MATHEMATICS—The Deputy Secretary, The University of Southampton, Southampton (January 29).

LECTURER IN THE SCIENCE AND TECHNOLOGY OF PRIMARY METAL PRODUCTION IN THE DEPARTMENT OF METALLURGY—The Registrar, University College of Swansea, Singleton Park, Swansea (January 29).

LECTURER OR ASSISTANT LECTURER IN APPLIED MATHEMATICS in St. Salvator's College—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (January 29)

EMBRYOLOGIST (scientist with research experience in embryology or developmental genetics)—The Director, The Poultry Research Centre, A.R.C., West Mains Road, Edinburgh, 9 (January 31).

LECTURER IN APPLIED MATHEMATICS; and a LECTURER (with a special qualification and interest in microbial genetics) IN GENETICS—The Secretary, The Queen's University, Belfast, Northern Ireland (January 31).

LECTURER or ASSISTANT LECTURER (preferably with a special interest in either sociological theory, or industrial sociology, or research methodology) IN THE DEPARTMENT OF SOCIOLOGY—The Assistant Registrar, Faculty of Commerce and Social Science, The University of Birmingham, Birmingham 15 (January 31).

LECTURER (preferably with research interest in geophysics) IN PHYSICS at the University College, Dar es Salaam (University of East Africa)—The Inter-University Council, 33 Bedford Place, London, W.C.1 (January 31).

LECTURER (with a good honours degree in agriculture, agricultural botany, agricultural science, rural science or botany, and research experience in the field of plant breeding and/or crop ecology) IN AGRONOMY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 4).

CHAIR OF THEORETICAL CHEMISTRY—The Deputy Secretary, The University, Southampton (February 5).

LECTURER or ASSISTANT LECTURER (with research interests in any branch of physical chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Deputy Secretary, The University, Southampton (February 5).

LECTURER or ASSISTANT LECTURER (with research interests in theoretical organic chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Deputy Secretary, The University, Southampton (February 5).

PROFESSOR OF GEOGRAPHY AT RHODES UNIVERSITY, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W 1 (South Africa and London, February 7)

LECTURER or SENIOR LECTURER IN MATHEMATICS, and a LECTURER, SENIOR LECTURER or READER IN STATISTICS at the University of Tasmania—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 11).

POPULATION GENETICIST (with a Ph D. degree in a relevant field or post-graduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability) IN THE DIVISION OF ANIMAL GENETICS, Commonwealth Scientific and Industrial Research Organization, North Ryde, Sydney, New South Wales, to work in the field of selection genetics—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W C.2, quoting Appointment No. 675/162 (February 12).

TURNER AND NEWALL RESEARCH FELLOWS IN ENGINEERING, INORGANIC CHEMISTRY, PHYSICS AND ALLIED SUBJECTS—The Registrar, The University, Manchester, 13 (February 14).

ASSISTANT DIRECTOR (with a degree in biological science, preferably in nutrition, physiology, zoology or biochemistry, experience in research in nutrition, and preferably a reading knowledge of languages and editorial aptitude) OF THE COMMONWEALTH BUREAU OF ANIMAL NUTRITION, Rowett Research Institute, Aberdeen, Scotland—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (February 15).

DEPARTMENTAL DEMONSTRATOR IN BIOCHEMISTRY—The Administrator, Department of Biochemistry, University of Oxford, South Parks Road, Oxford (February 15).

CHAIR OF PURE MATHEMATICS at the University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar of the University (New Zealand and London, February 28).

LECTURER/SENIOR LECTURER (with a degree in veterinary, agricultural or general science with special training or experience in physiology, and preferably some experience in teaching at university level) IN ANIMAL PHYSIOLOGY IN THE VETERINARY SCIENCE DEPARTMENT, Lincoln College (University of Canterbury), New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, February 28).

SENIOR LECTURER or LECTURER IN GEOMORPHOLOGY at the Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 28).

WILLIAM JULIEN COURTAULD CHAIR OF HELMINTHOLOGY at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Senate House, London, W.C 1 (March 11).

ASSISTANT PROFESSOR OF CHEMISTRY—Head, Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan, Canada.

BASIC GRADE BIOCHEMIST to work in a Metabolic Ward under Prof. Dent (previous experience in a metabolic field is not essential)—The Assistant Secretary, University College Hospital, Gower Street, London, W.C.1.

FOREST PATHOLOGIST (national of the United Kingdom or the Republic of Ireland, with a degree in forestry and relevant postgraduate experience) in Trinidad and Tobago, to carry out a survey of forest pathogens—The Appointments Officer, Ministry of Overseas Development, Room 301, Eland House, Stag Place, London, S.W 1, quoting Ref 324/178/03.

HISTOPATHOLOGIST (with either a veterinary or medical qualification); and a TOXICOLOGIST or PHARMACOLOGIST (recent graduate in pharmacology, pharmacy or zoology) in the APPLIED PHARMACOLOGY DIVISION, to be concerned primarily with the pathology and toxicology of drug induced lesions in experimental animals—The Personnel Manager, Arthur D. Little, Ltd., Inveresk Gate, Musselburgh, Midlothian, Scotland.

ORGANIC CHEMISTS and PHYSICAL CHEMISTS (with a Ph.D., a good honours degree, or H.N C qualification, and preferably under 30 years of age). The work is in many cases of a fundamental nature and every encouragement is given to publish the results and study for a higher degree—The Director, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian, Scotland

POST-DOCTORAL BIOCHEMIST (Lecturer grade) for a research group working on isoenzymes in normal and malignant tissues—Prof. D N. Baron, Department of Chemical Pathology, Royal Free Hospital, Gray's Inn Road, London, W.C.1.

RESEARCH ASSISTANT (preferably with experience of immunology or bacteriology) FOR A RESEARCH PROJECT—The Secretary, Institute of Clinical Research, Middlesex Hospital Medical School, 40 Hanson Street, London, W.1.

RESEARCH ASSISTANT (with a good honours degree) to work on bacterial genetics—Prof. G. G. Meynell, Guinness-Lister Research Unit, Lister Institute, Chelsea Bridge Road, London, S.W.1.

STUDENT TECHNICIAN IN THE DEPARTMENT OF FORENSIC MEDICINE, to assist (in a technical capacity) in a programme of research into the development of rapid methods of toxicological analysis—Dr. Harold V. Street, Department of Forensic Medicine, University New Buildings, Teviot Place, Edinburgh, 8.

SCIENCE AND THE NATIONAL PLAN

*THE National Plan**, covering all aspects of Britain's economic development for the next 5 years, was prepared in full consultation with industry, as well as in close association with the National Economic Development Council. It analyses the problems to be overcome in order to achieve a 25 per cent growth in the national product between 1964 and 1970, and in his foreword the Secretary of State for Economic Affairs, Mr. G. Brown, claims that the Plan is both a statement of Government policy and a commitment to action by the Government. It means also that industry itself must plan investment, manning and training to achieve this 25 per cent increase in output and, above all, it requires an acceptance of change from all concerned.

The Plan is outlined in an introductory chapter, following which the basis of growth is discussed in seven consecutive chapters, which deal with output and productivity; manpower; industrial efficiency; investment; prices and incomes; balance of payments; and regional planning. Six chapters on industrial sectors follow, dealing with engineering and allied industries; construction; energy; transport; agriculture; and with other industries. Under "The Use of Resources", there are eight further chapters on the use of resources generally; consumers' expenditure; housing; public expenditure; defence; health and welfare services; education; and benefits and assistance. Although the Plan was published in September, it was first presented to the House of Commons by Mr. G. Brown on November 3, when it was welcomed without division. It was discussed in the House of Lords on November 24, and it is in the light of these two debates that its features of scientific interest are appropriately considered.

On November 3, Mr. Brown said that the Plan was designed to achieve four main objectives. Besides accelerating the rate of growth it was to rectify the balance of payments. Thirdly, it was to secure a better regional balance of development, and fourthly, it was to ensure that the fruits of future growth were used in accordance with the needs of a civilized and just society. An effective policy for productivity, prices and incomes was an essential key to these four objectives, and, although the Government hoped that voluntary effort would suffice, it would reinforce voluntary effort by legislative power, if necessary. Mr. Brown recognized that much more information was required, but he hoped that by the middle of 1966 the councils and boards would be able to offer preliminary advice on how their regional resources could be better used, and on the broad policy objectives and strategy of development towards which regional planning should be directed. He referred to the large increase in population which could be expected between now and the end of the century, and emphasized the importance of changes in the distribution of Britain's industrial effort which could, meanwhile, accelerate economic growth.

This would involve co-operation at all levels, including greater mobility of labour, and in this connexion he referred to the manpower situation. The Plan itself forecasts an increase of 390,000 in the working population between 1964 and 1970, apart from any special measures. It is estimated, however, that by such measures, including a reduction of 50,000 in the number of unemployed, it should be possible to achieve an increase of about 600,000. Nevertheless, Mr. Brown said that consultations with industry had indicated that there would be a demand for some 400,000 people more than were expected to be available in 1970. Regional policies might reduce this deficit by half, but there would be a need to make much better use of manpower, particularly in those industries where, at present, over-manning and wasteful use of people existed. This was essentially a problem for industry itself.

Mr. Brown did not refer specifically to trained manpower, although in its preliminary report (issued in November) the Willis Jackson Committee on Scientific and Technological Manpower indicated its close concern with the efficient use of such resources. The National Plan itself has three short paragraphs on scientific and technological manpower, and it estimates the number of scientists and technologists employed in manufacturing industry in 1965 to have been about 300,000. This figure does not include about 1·2 million technicians and other technical supporting staff. The present gross annual increase in the number of scientists and technologists of about 20,000 is expected to rise to nearly 28,000 by 1970 and, here again, emphasis is placed on improved deployment and more effective use of such manpower; however, it is also anticipated that the Government's defence policy will release some technically qualified people for civil work.

Here the Plan refers specifically to the work of the Willis Jackson Committee on Manpower Resources for Science and Technology, and to the important role of the technician. Besides an enquiry into training requirements for graduate engineers in the manufacturing industries, the Ministry of Technology is sponsoring a study of factors affecting the status of engineers in society, and is also planning a survey, in conjunction with the Engineering Institutions' Joint Council, into the ways in which such personnel are employed. Clearly the long-term increase in productivity in Britain will depend heavily on the greater skill and technical proficiency of the labour force. There is a further reference to the manpower situation in the chapter dealing with education, where it is claimed that a great effort is being made to develop courses for technologists, technicians and others.

The Plan envisages an increase in current expenditure on further education from the 1964–65 figure of £125·9 million to £189·5 million by 1969–70, and in capital expenditure from £23 million to £46 million. It is expected that recurrent grants to the universities will rise, over this period, from £140 million to £209 million, and that non-recurrent grants will reach £356 million; building programmes in the period will be concentrated almost entirely on provision for extra students. These figures contemplate more than 70,000 places in technical colleges and other institutions of higher education in 1969–70 and about 199,000 university places, with 98,000 places in teacher training colleges.

This expansion itself represents a large demand for manpower, estimated at just more than 100,000 full-time

* *The National Plan.* (Cmnd. 2764.) Pp. xviii+474. (London: H.M.S.O., 1965.) 30*s.* net.

staff between 1964 and 1970, or a 25 per cent increase on that in 1964. This would represent nearly two-fifths of the increase during the period in the number of those with full-time higher education, apart from the substantial increase in non-teaching staff, which, in the universities alone, could be almost 20,000.

It is recognized that the manpower situation may involve some limitation on the expansion that is planned, but this was not mentioned by Mr. Brown, nor was the question of trained manpower considered in either debate, although there were several references to the general manpower situation. This is the more surprising in that the manpower situation, and especially the supply of trained manpower, is the key to the whole Plan—as appeared to be implicit in some of the criticisms of the Government's educational policy. Even if the forecasts for manpower are accurate and the net shortage is no more than 200,000, it should be remembered that this assumes both an industrial and a regional mobility of labour which has not yet been witnessed in Britain. It also assumes a geographical mobility of expanding industries to which serious obstacles exist, and also abstention from serious industrial disputes even by small minorities or groups. Mr. A. Albu, who wound up the debate for the Government in the House of Commons, admitted that the shortage of skilled workers was a much more serious problem than the total shortage of workers revealed by the projections of the Plan. He was content, however, to leave the remedying of this situation mainly to the Industrial Training Boards, with assistance from the Government in expanding training centres. He did not otherwise discuss the educational issue.

This issue was more prominent in the debate in the House of Lords. Lord Winterbottom from the start questioned the adequacy of the proposed increase in total expenditure on the universities, particularly in the light of the contemplated expenditure on drink and on entertainments and other services. Such priorities were also questioned by other speakers, such as Lord Drumalbyn and Lord Wade, but Lord Brown, the Minister of State at the Board of Trade, restricted himself largely to export questions, though admitting that the educational system had failed to bring home to young people the central importance of British industrial effort. In consequence, the ablest sixth-formers were still not sufficiently attracted to industrial careers, nor was this always corrected in the universities. This has had a considerable effect on the leadership of industry, from which Britain is still suffering.

This is indeed specifically recognized in the Plan, which states that the most intangible, and at the same time the most important, factor in improving industrial efficiency is the quality of industrial management. With the growing interest in management education, it is expected that expansion in this field, as well as improvements in quality, will make an important contribution in raising standards of management; the increased mobility of managers and the wider use of professionally qualified consultants should also help. The Economic Development Committees must be concerned with all aspects of effective management, if they are to achieve their objectives. They will need to examine the adequacy and effective use of research and development, the training and recruitment of staff, design, control of stock and quality, and marketing. Some of the Committees have already started to examine these problems and the Government's insistence on fuller disclosure in company accounts is stated to be aimed at stimulating greater awareness of the scope for improving the performance of management.

Besides the two new graduate Business Schools at London and Manchester, and the similar facilities now being provided or planned at other universities or institutions of higher education, it is suggested that more needs to be done for the young non-graduate, for the older manager, and for certain specialized requirements, such as small firms in the export market. A wider dissemination of the many special techniques, such as operational research, network analysis, value analysis, systems engineering, linear programming and other more advanced methods of appraising investment could also help. Interest in management questions within the Trade Unions is also growing, but while the Plan notes the two-week courses on production and management held each year at the Trades Union Congress Training College, and the other training arrangements in this field, it overlooks the effect on recruitment of the expansion of higher education which can significantly affect the quality of leadership unless officials are recruited to a larger extent from the universities.

The rationalization of the industrial structure increases the need and opportunity for specialized management expertise, and the Government is justifiably anxious to do what it can to increase the numbers of professionally trained managers in control of industry and commerce. This applies equally to the administration of the Trade Unions, and the opportunities for efficient management can be restricted unless the leadership of the Unions is also effective and efficient and the implications of the growing opportunities in higher education are fully appreciated. British professional standards are respected throughout the world, but if, in the past, industrial management as such has tended to remain somewhat outside the mainstream of professional life, an improvement in the efficiency and standing of management could do something to ease the whole question of labour relations and the reform of the Trade Unions themselves.

This point was firmly pressed by Lord Peddie in the House of Lords on November 24, particularly in reference to the removal of restrictive practices. He pointed out that the responsibility here did not rest solely either on labour or on management. Nevertheless, the initiative for reform rested fundamentally with management, which must increasingly take labour into its confidence and seek to convey some understanding of the basic ideas behind policy. This was essential to secure full co-operation, and Lord Hanley fully supported him in this emphasis on co-operation and on the importance of management education. Lord Cohen, also, emphasized the importance of education, as did the Earl of Dundee and Lord Shepherd (the latter replying for the Government in the debate), but here the criticism was directed rather at the curtailment, even if temporary, of university building expenditure and the criticism was not effectively answered by Lord Shepherd. Earlier, Lord Eccles had also questioned the soundness of this pause, but he had been much more concerned to refute any suggestion that education was not an end in itself, but an equipment for life, rather than, as the protagonists of the Plan seemed to imply, a tool for economic growth.

Two other points of some scientific or technical interest in the National Plan were raised in the House of Commons debate. A section dealing with Government action, in the chapter on industrial efficiency, refers at some length to the work of the Ministry of Technology. After a reference to the effect of heavier competition in establishing a more dynamic and efficient economy, to the stimulation of

technological innovation and to increasing the efficiency of the public sector, the Plan refers also to the way in which mergers may assist technological development and increase the scope for co-operation in scientific and technical research. Where Government initiative can promote such developments, the Ministry of Technology is its chosen instrument, and, especially in the application of the results of research, the National Research Development Corporation. The powers of the Atomic Energy Authority to undertake research and development have also been extended with a like end in view.

The application of technology depends largely on engineers, and many weaknesses of British industries and their failure to meet foreign competition adequately can be attributed to a shortage of engineers and to insufficient attention to engineering design. There is evidence that both the profession of engineering and design activity generally are failing to attract sufficient of the ablest school-leavers and university graduates. In this connexion, also, the Ministry of Technology has been assigned the difficult long-term task of co-ordinating activities which will help to raise the status of engineers and improve their training and deployment in industry. Here the Ministry's programme involves implementing the recommendations of the Fielden Committee on Engineering Design in co-operation with other Departments and organizations; in co-operation with the Confederation of British Industry, much has already been done to increase the awareness by management of the importance of design. The formation of the Engineering Institutions' Joint Council is a further important and constructive step, and the Ministry is discussing with several universities and colleges the establishment of institutes of advanced engineering studies. The Science Research Council is also assisting by sponsoring advanced design work at the Universities of Cambridge, Glasgow and Liverpool.

Besides this, the Ministry of Technology has been given responsibility for sponsoring the machine tool, electronics, communications and computer industries, and this responsibility has since been extended to the mechanical and electrical engineering industries as a whole. While, in some areas of industrial automation, British invention is to the forefront, it is urgent that the present position should be improved and automation technology developed and applied more generally. It is a major objective of the Ministry of Technology in the field of development to support projects which will demonstrate the technical and economic benefits of automatic operation and process control. Measures were also announced in March 1965 to give greater assistance to the computer industry in developing both hardware and software, to support university research, and to provide advice on computer procurement in the public sector and elsewhere. A short section of the Plan discusses some of the measures being taken to this end in the public sector generally.

It should not be forgotten that the policy outlined in this chapter of *The National Plan* and the organization chosen to achieve that end rests on some assumptions regarding research and development that, far from being generally accepted, are still the object of informed debate. Much of the structure established for civil research and development has as yet, to say the least, to prove itself. Nor are misgivings confined to scientific and technological circles. In its third report for the session 1964–65 the Estimates Committee was highly critical of the structure and competence of the Ministry of Technology (see *Nature*, 207, 1113; 1965). It is difficult to point to concrete evidence that the position has improved since the report was published in July, nor has it as yet been discussed in Parliament.

In this context, Sir Edward Boyle was fully entitled to ask in the House of Commons on November 3 if the Minister of State for Economic Affairs was really satisfied with what the Minister of Technology was doing, or should be doing, to further the application in industry of scientific and technical knowledge. Sir Edward questioned whether the new Ministry was any closer to industry than the Department of Scientific and Industrial Research had been, finding support for his view in that section of *The National Plan* which has been summarized here. He agreed that the Ministry should be striving to make the whole of industry more 'science minded', but it was obvious that Sir Edward thought that the Minister, if not the Ministry, lacked drive and, possibly, confidence. Nothing has since been said either in debate or public speeches to remove such doubts.

The second point relates to fuel policy. This is considered in the chapter of the Plan devoted to Energy, which was written in advance of the White Paper on Fuel Policy, published in October. So far as policy is concerned, it does no more than emphasize the importance of freedom of choice for the ultimate consumer in helping to keep down fuel costs and of the endeavour, in recent years, to moderate the impact on coal of competition from imported fuels. It admits that, in the long term, a major uncertainty is the part that natural gas will play and that further imports on a large scale or the discovery of large quantities in the British part of the North Sea Continental Shelf could radically change the energy position in Britain. Nothing in this chapter, however, gives any hint that any more vision and determination have gone into the National Plan in this vital sector than in the subsequent White Paper, and Mr. Ian MacLeod's criticism on this point in the House of Commons debate was largely justified. It is not simply that the assumptions made by successive Governments in the field of fuel policy for many years have been consistently wrong. There has also been a persistent failure to face the difficulties and implications arising out of the clash of interests between Departments and the nationalized fuel industries.

This is a criticism of all recent Governments and, in that sense, this is not a matter of party politics. It illustrates, however, the extent to which the issues arising in national planning are technical and factual and are not to be resolved by means shaped primarily to suit a political ideology. Fuel policy, in fact, brings us back to the real gravamen of the criticism which has been made of the Ministry of Technology. It is not simply that there are good reasons for questioning whether the soundest possible structure has been established for Britain's effort in civil research and development. The structure might work, even if imperfectly, provided due regard were paid to the vital criteria for assessing the balance of the effort, the choice of projects and the conditions of effective scientific work. These have been admirably set forth in papers by G. B. Kistiakowsky and Dr. A. M. Weinberg, which have been discussed recently in these columns (*Nature*, 209, 1; 1966).

What is disturbing is the lack of evidence in the Plan, or elsewhere, that these conditions are appreciated by the Government, or that it is prepared to make the continuous allocation of resources, free from limitations or 'stop–go' restraints, which are essential for Britain's continued

advancement. Mr. Brown will find that the real test of the National Plan will lie in the way in which it channels the national effort, and not the least the way in which it affects the civil research and development effort.

PANGLOSS OR PLOTINUS

The Uniqueness of Biological Materials

By A. E. Needham. (International Series of Monographs in Pure and Applied Biology. Division: Zoology, Vol. 25.) Pp. xix + 593. (London and New York: Pergamon Press, 1965.) 100*s*. net.

A FEW years ago those who followed in the footsteps of L. J. Henderson and argued that the properties of elements and compounds were adapted, to an extent that was unlikely to be accidental, to the requirements of life and that therefore our form of life was likely to be the only one, had little reason to fear refutation. It takes rather more self-confidence to argue this case now, for space travel could produce contradictory evidence. Those who maintain that Henderson paid insufficient attention to the probability that, in evolving here in the way it did, life exploited the existing situation opportunistically, and could be different in a different environment, are still on reasonably safe ground; they can 'have it both ways'. If organisms should be found on another planet that depend on a basic biochemistry similar to that used on Earth, it may mean no more than that both have come (or just conceivably have been sent) from a common source. If an alien form of life should be found, our case will be proved. The two (or more) systems might be called chthonobiology and xenobiology, and the investigation of the extent to which each is adapted to local conditions will make a fascinating study.

While waiting for the possible start of this extreme form of comparative biochemistry, it is as well to survey the extent to which organisms have adapted themselves to local conditions and exploited all chemical potentialities. Needham attempts this comprehensibly and, on the whole, successfully. *The Uniqueness of Biological Materials* is not without faults: there is a great deal of matter in it with no obvious relevance to the theme, there are several factual errors, and the citing of references is capricious. Too many references are to secondary or even popular sources, and often relate to matter that is dealt with in text-books, whereas interesting, and sometimes improbable, statements slip in with no authority. Nevertheless, it is a serious and original attempt to deal with an important subject and represents the fruit of a vast amount of reading.

Three-quarters of the book is devoted to carbon compounds. Those aspects of biochemistry that are nearly universal are outlined and some of the more intriguing by-ways are mentioned. Needham not only discusses the molecules that are used but also those that are not—or that are used rarely. This is fundamental to the proposition implied by his title. The frequent reappearance of the same molecules could arise because these are the only ones able to bring about the required reactions effectively; because the dependence of organisms on one another in food chains forces the later links in the chain to comply with the pattern defined by the first member; or because, once a molecule is established in a well-integrated enzyme system, natural selection will tend to eliminate a variant, even if it uses a potentially better molecule, during the phase in which enzymes adapted to the new molecule are evolving. These points can be explored experimentally. Thus the diversity of phosphagens used in different phyla shows that different molecules can perform a similar function, but it is still by no means clear what advantage, if any, each has in the phylum in which it occurs.

The general use of L-amino-acids in proteins is reasonably satisfactorily explained by invoking food chains and the greater instability of polymers containing both isomers compared to those containing only one. It is more difficult to explain the preference organisms show for the same twenty amino-acids. It would be interesting to know whether polymers containing some of the excluded amino-acids, for example, L-α-amino-butyric acid, have any anomalous properties *in vitro* that could justify the exclusion. It is well known that an amino-acid substitution, azetidine carboxylic acid for proline, or valine for glutamic acid, gives rise to a significantly different protein —but still a protein. Before we regard the usual amino-acids as unique we should know whether a polymer containing a significant proportion of the excluded amino-acids would be a protein at all.

The elements other than carbon are, naturally, considered in less detail. The manner in which the properties of such elements as iron and calcium adapt them for their observed biological roles is outlined. These are common elements, so their general use is comprehensible; the rare use of such elements as barium, strontium and vanadium is more difficult to understand. Is this rarity simply a consequence of their patchy distribution on Earth's surface; or are these elements, in spite of the antiquity of the species that use them, intrinsically less suitable? This book gives no answer but, by presenting the evidence, it usefully calls attention to the existence of the problem. In the course of this discussion the conclusion is reached that biological processes do not alter the properties of the elements. That will be generally agreed, but it is surprising to find the issue discussed at all; one had thought the possibility was mooted only by those who think that the fluoride ion has different properties when coming directly from underground rather than from a bag, or that 'fixed' nitrogen differs in some way from that in dung.

The biochemical aspects of biology depend, in essence, on the interplay between morphology and enzyme action. If we bear in mind the observed rate of dimensional change (4 per cent or more per million years), the plasticity and flexibility of proteins (exemplified by the ability of antibodies to conform to an immense range of antigens), and the 2,000 million years that have apparently been available for evolution, the observed congruence between chemical potentialities and the needs of organisms seems to raise no difficulties. The number of possible proteins is so vast that it is reasonable to expect them to cope with any chemical reactions that have possible 'survival value'. On this view our present state may not yet be "the best in the best of all possible worlds", but we are heading there. The rival view is that the congruence is improbably good; it leads to the concept of design, or to Plotinus's thesis that organisms and the basic properties of the environment act reciprocally on one another. The observations made so far do not seem to force on us so radical an overthrow of accepted scientific canons. N. W. Pirie

LUNG CIRCULATION

The Lung Circulation

By Prof. Domingo M. Aviado. Vol. 1: Physiology and Pharmacology. Pp. xxiv + 1–590. Vol. 2: Pathologic Physiology and Therapy of Diseases. Pp. xix + 591–1405. (London and New York: Pergamon Press, 1965.) 300*s*. net, per set.

UNTIL recent years the pulmonary circulation was not a popular subject of investigation among either physiologists or clinicians. This was due, in part at least, to a lack of interest and the belief, generally fostered by text-books of physiology, that the pulmonary circulation is effectively independent of the nervous system or of any humoral control. It had been repeatedly shown from the late nineteenth century onwards that pulmonary vasomotor responses could be excited by both nervous and hormonal stimuli, but such evidence was generally

dismissed on the grounds that the responses were too small to be significant and that, in any case, since all blood must flow through the lungs, imposed changes in the resistance of the lung vessels would serve no useful purpose. This is still a difficult argument to meet, but, as readers of *The Lung Circulation* may see for themselves, it is possibly no longer of great importance. Now it is not so much a question of whether control exists but by what mechanism it is made effective. For this new attitude a great deal of credit must be given to both Liljestrand and Cournand, the former because of the post-war investigations initiated in his department on the pulmonary vasomotor effects of ventilation hypoxia and hypercapnia, the latter because of his influence and example in developing techniques for the examination of the pulmonary circulation in man. The great improvement in technical facilities and instrumentation has undoubtedly also contributed to the increase in research on the circulation of the lungs. How accelerated this has been may perhaps be appreciated from the fact that the author of this book has quoted from about 7,000 papers, 80 per cent of which have appeared in the past 15 years. Those who know how sparse was the pre-war literature on this subject will appreciate the contrast.

The author of these volumes, Dr. Domingo Aviado, with his colleagues at the University of Pennsylvania, has himself made a distinguished contribution to the pharmacology of the pulmonary circulation during the past 15 years and, from his knowledge of the problems involved, both technical and theoretical, is well qualified to write about this subject. It is remarkable, however, that he should also have managed to write so informatively about many other aspects of the lung circulation in disease as well as in health.

Containing more than 1,200 pages of text, the book is divided into two volumes comprising five sections. The first section (*A*) deals with the effects of ventilation hypoxia, the evidence for baro- and chemo-receptors in the lungs, the bronchial circulation and the evidence for the release of certain chemicals, 5-hydroxytryptamine and the like, from lung tissues. Section *B* deals with the action of drugs which either imitate or alter the action of autonomic nerve stimulation. Section *C* takes up the actions of a comprehensive list of vaso-active drugs of clinical and scientific interest. Next (*D*) comes a discussion of acute pulmonary diseases and (*E*) of chronic pulmonary hypertension. The discussion throughout the five sections is linked together by the emphasis placed in each on the idea that the blood vessels of the lungs behave as any other blood vessels in health and disease and are under similar controls.

As a reference work, teachers and clinicians cannot help but find it a useful text. The information about the action of drugs must alone be considered a valuable contribution; but the account of the clinical observations made on the human lung in the past 15 years is equally valuable. For those who want to find out more about the use of such observations, and the techniques utilized, the book provides plenty of references.

Physiologists who have studied the problems treated in the first two sections may not agree with all the author's ideas. One cannot help but feel that there has been too great a desire to bring all information under one theoretical umbrella. There are large areas of theory which have very little experiment to reinforce them. But whatever one may think about individual arguments and interpretations, the total structure built up is impressive and cannot fail to interest and stimulate other investigators in the field.

A welcome subject of discussion in the book is the bronchial circulation. This adds greatly to its value. Except in some specialized anatomical treatises there are few accounts of this system of vessels, although, because of its nutritive function and because of its connexions with the pulmonary vessels, it has great functional importance. As Daly showed over thirty years ago, for experimental investigations of the innervation of the lungs the bronchial circulation must be maintained or the nerves will die. Extensive communications between pulmonary and bronchial circuits also mean that haemodynamic events within either circuit may affect the other; this factor must be borne in mind when pulmonary vasomotor responses to any stimulus are under test. There are obviously good reasons why account must be taken of the bronchial circulation when planning experiments on the pulmonary circuit, but a knowledge of the bronchial circulation is also of clinical importance. Its reactions and growth changes in pulmonary disease constitute one aspect of its clinical relevance; another is the significance of the bronchial circulation as a nutritive system of vessels to a number of lung structures. The author should also be commended for giving a fair and balanced account of broncho-pulmonary anastomoses. It is sometimes a temptation to think that one function of pulmonary vasomotor control may be in the opening and closing of precapillary anastomoses between the two systems; maybe it will prove to be so; but, as the author emphasizes, the evidence that these connexions exist is still controversial.

It is a disappointment that the chapter on the autonomic control of the pulmonary circulation is largely a discussion of drugs and that the direct evidence from experiments on the effects of stimulating the nerve supply of the lungs is given such cursory treatment. There is an extensive literature dealing with this question which goes back to the nineteenth century, and one cannot but wonder a little whether the author does not lack a sense of proportion when, as evidence that sympathetic nerve stimulation increases pulmonary blood flow and pressure and pulmonary vascular resistance, he quotes a paper of his own written in 1961 and another by a Japanese author written in 1962. It is here that one would expect I. de B. Daly to get honourable mention, but at this stage his work is quoted only in support of some minor points in the exposition. In any event, the title of the chapter is misleading, since the author evidently had no intention of discussing the innervation of the vessels as such. What is more serious is the superficial treatment of the pharmacological evidence. The author concludes that the simplest concept is to regard acetylcholine as having a dilator action on all blood vessels, pulmonary and systemic, even though most of the classical evidence, including some quoted by him, shows that it can be both pulmonary vasoconstrictor and vasodilator in a number of species. Such theoretical treatment is not very helpful.

In certain respects the presentation is confusing. The reader will very often find it difficult to know which evidence has been obtained by Dr. Aviado himself and which is being quoted from others. Statements which seem to be theory only are made as if they were authenticated experimental fact. When, as I suppose will happen, this book comes to a second edition, these points might well be rectified. Similarly, it would be helpful if, under figures taken from journals, the authors' names were quoted. Presumably most of those used were from Dr. Aviado's own papers; even so, it would be helpful to know. The figures would also be easier to understand if the tracings, such as those of Fig. 1.5, were always labelled.

Line drawings appear in many parts of the text to illustrate or summarize methods or ideas. Some, such as Fig. 7.1, are moderately successful but it must be admitted that many are less successful. In some cases this is simply because the lettering is insufficient or insufficiently explained (see Fig. 1.9) and the diagram itself is not inspired enough to help the reader over the difficulty. Other figures such as 5.9 seemed pointless to me; this one simply indicates a few of the well-known actions of histamine, suggests that it can be released in three parts of the circulation and from any one is likely to be carried

to either of the others. An elaborate diagram to make these points seems unnecessary.

Fig. 6.3 deserves a special comment. It is a good idea to carry the same pressure-flow diagram through the book and to explain its meaning at the beginning. The idea would be even better, however, if it were made clear there and then that the symbols explained, but not used in it (Fig. 6.3), are the ones which will appear in succeeding diagrams of which it is the prototype. Otherwise, readers who like to understand each stage of an argument before going on to the next may spend more time than they should looking for the lost symbols on or around p. 330. Nevertheless this is a useful idea and should be commended.

Chapter headings have not always been well chosen. The one beginning "The Release of Chemical Substances" (Chapter 5) has comparatively little evidence about the actual release of the various substances discussed. It affords a lot of evidence suggesting that, if such agents as histamine, 5-hydroxytryptamine and others are released, then they would act on the pulmonary vasculature in various ways. Under certain circumstances some evidence of the release of histamine can be obtained, but it remains to be shown whether this normally happens in such a way as to produce responses of the lung muscle. Even less is known about the normal functions of the other substances discussed, but the tone of the discussion here seems to imply that the various agents considered are in fact concerned in the regulation of the lung circulation. Far more evidence will be needed before these views can possibly be considered seriously.

There are some inaccuracies, and signs that some of the papers referred to have not been read very carefully. For instance, it is implied on page 9 that Beyne was the first to test the effects of anoxia uncomplicated by asphyxia on the lungs. In fact, the credit for this should go to Plumier, whose experiments were published nearly forty years earlier. Again, on page 156, Duke *et al.* are quoted inaccurately and the point in their paper that excess CO_2 is not itself an adequate stimulus for the postulated chemoreceptors of the pulmonary artery is missed. It is a pity, too, that in dealing with the effects of anoxia the author fails to make clear to the reader the essential differences between experiments done on the completely isolated perfused organ and those done on lobes or single lungs perfused *in situ*. In the latter, not only the innervation of the tissue but its bronchial blood supply is intact, and the influence of the heart on the venous pressure and drainage may introduce other haemodynamic variables.

In the context of the total achievement of the book these criticisms are minor ones. It has to be remembered that this is the first book of the kind to be written about the pulmonary circulation and, whatever one may feel about some of his individual judgments, there is no gainsaying that the author has managed to present a coherent and logical account of the subject and that he is in full command of his material throughout. Moreover, the discussion is generally lively as well as informative. Those who are interested in learning about the lesser circulation will find a great deal to the purpose in this book; others who are already indoctrinated will be grateful to Dr. Aviado for his extensive analysis of the recent literature and will find *The Lung Circulation* a useful addition to their bookshelves.

Catherine Hebb

VITAMIN ASSAY METHODS

Vitamin Assay

Tested Methods. By Rolf Strohecker and Heinz M. Henning. Translated by D. D. Libman. Pp. 360. (Weinheim/Bergstr.: Verlag Chemie, G.m.b.H., 1965.) 48 D.M. ; 12 dollars.

THE subject of *Vitamin Assay : Tested Methods* must be of importance to many workers in laboratories, both industrial and academic, throughout the world. The number of methods and modifications of methods advocated in the literature has reached a forbidding total, and many workers have their own favoured procedures which are often not generally available. It is useful, therefore, that tested methods in collected form should be made available to English readers, the more so since books on this topic appear to be surprisingly few.

An accurate knowledge of the content of vitamins in drugs, foods and feeding-stuffs has assumed great importance at the present time. The assay of vitamins in drugs is relatively simple, since the free vitamin is normally present and the separation of concomitant and possibly interfering substances is not usually unduly complicated. In foods and feeding-stuffs the preparation of an extract containing essentially the free vitamin is often a much more protracted procedure than the actual estimation itself.

Biological methods—the direct appeal to the animal—are probably the best in theory; but they have serious disadvantages in respect of time, space and cost, without concomitant compensations of precision and accuracy. Nevertheless, in some cases, notably that of vitamin D, it is still necessary to resort to biological methods. Chemical and physico-chemical methods are more speedy and precise, and microbiological methods for the B group of vitamins are likely to be at least as precise and of higher specificity. Owing to the exacting requirements of microbiological assay, only a limited number of organisms is available, but it is desirable, if possible, to use those which have similar nutritional requirements to those of man and animals. The increasing use of protozoa (for example, *Ochromonas malhamensis* for B_{12}) is a step in the right direction.

The limits of error in any of these methods are such as to cause some surprise to the academic chemist as they are often between $\pm$ 5 per cent and $\pm$ 10 per cent, and may range as high as $\pm$ 20 per cent. Indeed, in a recent collaborative report the 'between laboratories' limits were no better than $\pm$ 35 per cent.

The authors describe in detail methods for the assay of all the vitamins likely to be encountered. Preliminary separations are given in full, and valuable recent techniques—spectrophotometric, polarographic, fluorimetric, chromatographic (column, paper and thin layer)—are called in to the aid of the analyst. An interesting variation —'streak' chromatography on paper—is described in connexion with nicotinic acid, vitamin C and vitamin D, whereby larger volumes can be applied than in the case of the more usual 'spots', with better separation and more rapid working.

The determination of the content of a given vitamin, adequate in the case of pharmaceutical preparations, can be subtly misleading where the real nutritional value of foods or feeding-stuffs in respect of vitamins is in question. For example, in the case of vitamin E, the assessment of α-tocopherol or of total tocopherols is scarcely adequate since to obtain a complete picture of vitamin E activity it is desirable to know the proportions of some seven or eight tocopherols, a sizeable analytical problem which has by no means reached a final solution.

Example calculations, often regrettably omitted in original papers, are a valuable feature throughout the volume, although, somewhat surprisingly, there appear to be no indications of the importance of design of microbiological assays, and subsequent statistical treatment of results. It is also surprising that there is no description of cup-plate techniques which have been widely used for routine determinations in Britain.

Principal references are given at the foot of the appropriate page and there is a short bibliography in the appendix. This also includes a comprehensive list of reagents and stock solutions required in microbiological assays and the composition of media in tabular form.

The usefulness of this volume of tested methods, under the sponsorship of Merck AG, is not in any doubt and it

should find a ready welcome wherever vitamin assay is practised. It is finely printed and produced and includes clear diagrams, together with photo-reproductions in black-and-white, and good colour, notably of column and thin-layer chromatography. F. W. NORRIS

DEVELOPMENT AT THE CELLULAR AND MOLECULAR LEVEL

Molecular and Cellular Aspects of Development

Edited by Dr. Eugene Bell. Pp. xi+525. (New York and London: Harper and Row, 1965.) n.p.

THERE must be many who have been disappointed at the past failure of embryologists and geneticists to establish a common front in the battle for an understanding of the role of the gene in ontology. It looks now as if neither, but rather the molecular biologists, are going to be in the front line when the day of the breakthrough dawns. We may have been foolishly impatient in our expectations, overlooking the methodological hurdles in the way of such a straightforward synthesis of genetics and embryology.

The minute analysis, both of the synthetic processes in the development and growth of a complex organism and of the chemical nature, spatial exposition and behaviour of the 'gene' had to await new and dramatic developments in biophysical and biochemical instrumentation, including the advent of the electron microscope. Only then could the stage be set for bridge-building. When this finally happened the molecular biologists naturally had to take the lead.

The collection of fourteen chapters on the theme of *Molecular and Cellular Aspects of Development*, collected and edited by Dr. Eugene Bell of the Massachusetts Institute of Technology, represents an attempt at a synopsis by no fewer than eighty contributors of progress in the following fields: the study of cell association, induction, cyto-differentiation and cell division, the role of the nucleus, chromosome differentiation, genetic control of differentiation, isozymes, enzyme regulation, RNA synthesis, the synthesis of cell-specific products, macromolecules as the basis of structure, hormones, growth substances and cell-virus interaction. The central topic of the book is cell differentiation, although a number of articles deal also with tissue and organ development. Each of the chapters is introduced by a résumé by the editor covering the problems which form its main theme. The papers themselves are reprints of published articles by outstanding representatives in the field in question.

It is obviously impossible in a short review of such a complex work to deal with any of the individual contributions. Nobody can deny the great difficulties in the dissemination of scientific information, and any attempt to ease access to it ought to be welcomed. The alternatives are a comprehensive review by a single author from a central vantage point, or a herding together of systematically related papers into a work like the present synopsis.

The editor states that he has used this collection of papers for a first course in developmental biology at the Massachusetts Institute of Technology. This is remarkable in view of the rather advanced nature of most of the articles. In browsing through the various chapters, one becomes deeply conscious of the ebullient sense of adventure in present-day biology and of how good it is to be able to witness all this. The challenge of attempting the near impossible that has to be accepted in experimental ventures into the realm of molecular happenings, the unfolding of undreamt-of complexities in the form of interlocking self-regulatory systems, the satisfaction to be gained in the design of ingenious experimental and intellectual stratagems, the continuous call for self-criticism in the evaluation of inherently ambiguous observational and statistical results against the backcloth of the great fundamental generalizations governing our theorizing about gene action in the synthesis of proteins and other 'bio' materials, the ordered chaos of tissue and organ determination in embryonic development—of all this the reader of this book is constantly and excitingly made aware.

Extensive lists of references and 234 well-produced illustrations add to the value of the book, but, apart from a list of contributors, there is no index. The editorial prefaces to the individual chapters read in sequence give coherence to what could otherwise appear to be a rather haphazard collection of reprints. O. LOWENSTEIN

COMPUTERS IN MEDICAL RESEARCH

Computers in Biomedical Research

Vol. 1. Edited by Ralph W. Stacy and Bruce D. Waxman. Pp. xxii+562. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 160*s*.

"IN the space of a few years biomedical computing and automatic data processing have become a significant part of the biomedical scientific effort . . ." This assertion, carried on the dust-cover, is just. An increasing number of important problems in molecular biology, physiology, cardiology and other branches of medicine and its allied sciences are soluble only by extensive mathematical or numerical analysis. Many questions in clinical, social and administrative medicine can be answered only by large-scale data processing. Within the past half-decade computers have become not only more powerful and more numerous, but, through the introduction of automatic programming languages, more easy to use. A few pioneers have shown the potentialities of computer science in a wide range of medical applications and have thereby kindled a flame which must grow rapidly in the years to come.

Much of this work has been difficult to follow for those not centrally engaged on it. The publications are scattered and often assume considerable prior knowledge of computer science or the particular field of application. A number of symposia have appeared recently, particularly from the United States, but the presentations have often been too sketchy. *Computers in Biomedical Research*, Volume 1, and its forthcoming companion, Volume 2, appear to provide the best set of expository papers so far. The range covered is wide and most of the topics are discussed in some depth. Even here, however, a reader like myself, on the fringe of the subject, is likely to have difficulty in entering fully into such diverse topics as enzyme systems, protein structure, statistical analysis, personality assessment and neural processes. The specialist in one of these topics, on the other hand, is likely to ask for more detail, particularly about computing procedures, than can be given in these chapters. Perhaps we now need a series of monographs, each treating one field of medical computation in full detail.

An excellent introduction by the editors is followed by 22 chapters arranged in sections devoted to the life sciences generally, the simulation of biological processes, the analysis of specific systems, and applications to neurophysiology, clinical medicine, psychology and psychiatry. It may be useful here to classify the chapters according to the use to which the computer is put. Three chapters describe extensive data-processing systems: in laboratory medicine (B. G. Lamson), in pre-symptomatic screening for many diseases simultaneously (M. F. Collen, L. Rubin and L. Davis) and for automatic personality assessment (H. P. Rome *et al.*). Several chapters are concerned with complex calculations for diverse purposes: genetics (K-I. Kojima), protein structure analysis (C. L. Coulter),

statistical analysis (W. J. Dixon—it should be mentioned that the BMD programmes described here are written for the IBM 7090), and calculation of radiation dosages (T. D. Sterling and H. Perry). A group of chapters is concerned with the investigation, by calculation and simulation, of models of biological systems; mathematical aspects are discussed by G. B. Dantzig, simulation by D. Garfinkel, analogue computers by J. E. Randall, hybrid computers by W. Siler, neurotic systems by K. M. Colby, neural networks by B. G. Farley, and perceptrons by J. A. Daly, R. D. Joseph and D. M. Ramsey, and L. Uhr has a general chapter on model building. Two papers are concerned with cybernetics (F. S. Grodins) and computer-controlled experiments in psychology (G. A. Miller, A. S. Bregman and D. A. Norman). A group of chapters describes the use of computers for the processing of bio-electric signals: in neurophysiology (W. R. Adey, M. A. B. Brazier), cardiology (H. V. Pipberger), and foetal cardiology (E. H. Hon). Finally, L. B. Lusted has an excellent chapter on medical diagnosis. Many contributions are, of course, broader in scope than is indicated by the above summary.

This book is a stimulating guide to present-day American work on medical computing and the second volume will be awaited with interest. P. Armitage

CHROMOSOMES OLD AND NEW

Cytology

By Prof. C. D. Darlington. Part 1: A Reprint of *Recent Advances in Cytology*, Second Edition, 1937. Part 2: Recent Advances in Cytology, 1937–1964. Pp. xvi+768+16 plates. (London: J. and A. Churchill, Ltd., 1965.) 60*s*.

THE two pre-war editions of Darlington's *Recent Advances in Cytology* are undoubtedly classic texts, which were outstandingly successful in achieving what they were intended to do. This was the provision of a detailed account of chromosome form and behaviour, both normal and abnormal, in plants and in animals. They incorporated major syntheses of the literature of the field, built into a framework of interpretations and ideas developed by the author. They combined, in Prof. Darlington's unique style of writing, information with interest, wit with wisdom. The essential uniformity of the chromosome mechanism in both plant and animal kingdoms was emphasized throughout and an eye was always kept on the genetic roles of the chromosomes. The chromosomes contained the genes, indeed they were the genes, and were in turn subject "*as individuals to the laws they enact as a body*".

It is a measure of the stature of *Recent Advances*, and the value of the author's approach, that, despite its second edition being almost thirty years old—a great age for a book in a subject advancing as rapidly as cytology—it is a volume which must still be consulted by a practising cytologist as an authoritative basis for chromosome study. This continued demand has now been met, under the abridged title of *Cytology*, with a reprint of the second edition, originally published in 1937, supplemented by an appendix in which Prof. Darlington provides an assessment of the advances which have taken place in the field between 1937 and 1964. This very much shorter second section is not meant to have the detail and approach of the first section. Rather, it is a guide to those developments during the past twenty-seven years which have been of particular interest to the author himself and which support, qualify or, occasionally, disprove information or predictions outlined in the first section of the book. This personal approach lends coherence to the two sections and yields a result which is in many ways preferable to an attempt to combine the two in an entirely re-written edition. For this is not really a book for the beginner in cytology: the treatment of some topics is too detailed for this purpose and a number of introductory books, including some by the author himself, are more appropriate for this purpose. No, this is a book for the more serious student of chromosome cytology, who will be able to trace within its pages the development both of this important branch of biology and of this important biologist. I feel sure that all who fall within this category, including many who already possess one of the earlier editions, will wish to avail themselves of this new opportunity to survey the field from so respected a point of view.

S. A. Henderson

METEOROLOGY IN THE TROPICAL PACIFIC

Cloud Structure and Distributions over the Tropical Pacific Ocean

By J. S. Malkus and H. Riehl. Pp. ix+229. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1964.) 60*s*.

THE wide expanse of the central Pacific is a fruitful region for research in tropical meteorology, unhindered by the often overpowering effect of local orographic features. The two authors are well known for their published papers on the trade-wind regions. Whether they were wise to attempt a more detailed presentation in book form is questionable. For *Cloud Structure and Distributions over the Tropical Pacific Ocean* is simply a detailed account of observations made on three flights in 1957; it has taken much longer to appear, and will, one suspects, attract fewer readers than would a briefer account in a scientific journal. The flights were made at low level in a single aircraft, and observations were accordingly limited. Synoptic scale analyses must be considered subjective, and it is the meso-scale features that carry most interest.

The three tracks chosen were in a generally east–west direction just inside the Tropics; a north–south direction across the equator would have yielded results even more intriguing and difficult to interpret. However, the situations described are full of interesting detail. For example, the familiar 'lean' of trade-wind cumuli was found to be indicative of weak convection at the shear level; a change to more intense convection occurred due to the building of 1 in 4 of the cumulus lines at the expense of others; the cloud streets were at times related to the upper shear rather than the low-level wind, indicating that cloud observations from satellites should not be used in wind analyses.

On the larger scale, a remarkable feature of tropical Pacific meteorology is the high variability of flow pattern above the settled trade-wind flow. Data presented here seem inadequate for the theories advanced—Doppler winds from high-level aircraft were needed to supplement the scattered radar-wind reports. Nevertheless, the authors present a good case for relating the 250–150 mbar thickness tendency to large-scale development. I have noted that, on occasion, disturbances at 200 mbar are accompanied by unsettled weather, but more frequently there appears to be little association. More investigations of wind in the upper troposphere are needed in these regions.

All the data are well presented with full documentation of observations, including cloud photographs, together with appropriate synoptic charts and radio-sonde reports. It is a relief to find that the stream-lines illustrated do not reproduce the rather fanciful patterns to be found in other studies of tropical meteorology. After reading of these three flights one realizes the wealth of meteorological knowledge which must be acquired by airline pilots and which so rarely seems to be channelled through to the meteorologist. P. Graystone

Science in Nineteenth-Century America

A Documentary History. Edited and with an Introduction by Nathan Reingold. (American Century Series.) Pp. xii+339. (New York: Hill and Wang, 1964.) Cloth 5.95 dollars; Paper 2.45 dollars.

THIS collection of documents from nineteenth-century America is designed to help us understand the "present American eminence in the sciences".

The documents are, for the most part, private letters and personal records not intended for public consumption. They begin with the writings of Benjamin Silliman, sen., and Nathaniel Bowditch—both essentially popularizers with an eye to the practical application of science.

A majority of the American scientists during the nineteenth century were natural historians and explorers. Their work was inspired by the needs of a new continent and of a young country. Geophysics and meteorology thus became established as separate disciplines. With the advent of Darwinian evolution, however, the natural historians turned into biologists. With the rise of modern physics towards the end of the nineteenth century in Europe, the American explorers changed their interest from the physical world to the world of physics.

The founding of the National Academy of Sciences in the middle of the Civil War was undoubtedly a main event in the scientific life of the country. The Academy never played as important a part as the Royal Society did in Britain; its difficult origins may have held back the growth of the Academy.

Apart from Agassiz and Asa Gray, few of the American scientists were of international stature. It is only at the end of the century that native genius made itself felt. The physicists Newcomb, Rowland and Michelson were undoubted leaders in their field. Charles Sanders Peirce and J. Willard Gibbs are the two scientists who are outstanding in the originality and universality of their minds. Their genius has become recognized only in recent years. Peirce's contribution to a wide range of knowledge is not yet sufficiently appreciated, at least in Europe.

There was a prevalence of practical and a dearth of theoretical scientists during the earlier period. The flowering of American science at the turn of this century—and ever since then—was caused by the fertilizing contact with European science. It would be wrong to be blind to the fact that science is, and always has been, international. The present success of American scientists is built on, and impossible to divorce from, the achievements of the scientists of Western Europe and, indeed, of every part of the globe.

E. H. HUTTEN

Recent Advances in Selenium Physics

Edited by European Selenium–Tellurium Committee. (A Symposium on Solid and Liquid State Selenium Physics arranged by the European Selenium–Tellurium Committee and held at the Chemical Society, London, June, 1964.) Pp. vii+160. (London and New York: Pergamon Press, 1965.) 80*s*. net.

SELENIUM is the oldest of semiconductors and is still widely used as a rectifier material, in spite of the success of silicon and germanium diodes. One would imagine that the physical properties of selenium would have, by now, been fully understood but, in fact, they are still being actively investigated and it appears that much work remains to be done. The symposium which is reported in this book allowed a large proportion of those who are engaged in selenium research to meet one another, relatively few of the participants having less than a direct interest in the material. Not unexpectedly, the discussion was particularly lively, and forms a most valuable part of the report.

Most solid-state physicists nowadays are unhappy if they cannot work with single crystals, and four of the papers are devoted to the growth of crystals of hexagonal selenium; the work of D. E. Harrison in this field has been exceptionally successful. Most of the remaining papers discuss transport and optical measurements and their interpretation. It is quite clear that many of the established semiconductor concepts must be discarded for selenium, because of its very low carrier mobility. However, it is probably an example of a wide class of materials, and, being an element, may make an excellent prototype for testing theoretical ideas. In summarizing the symposium, H. Gobrecht points out some notable deficiencies in the work to date. Most important, the selenium used in the experiments has often been of doubtful purity. Surprisingly also, the atomic weight of selenium is known only to two decimal places.

Although the sub-title of the book mentions liquid selenium, there is only one paper devoted specifically to it (other than the consideration of its properties as relating to the growth of crystals). Only two of the papers discuss applications of selenium (in xerography and thermoelectricity, and in the latter field selenium is important only in compound form). It would not be unexpected, however, if the commendable encouragement of selenium research by the European Selenium–Tellurium Committee were to lead to new applications of a fascinating substance.

H. J. GOLDSMID

Evolution of Mathematical Thought

By Prof. Herbert Meschkowski. (The Mathesis Series.) Pp. 157. (San Francisco, London and Amsterdam: Holden-Day, Inc., 1965.) 6.55 dollars.

THIS translation of *Evolution of Mathematical Thought* adds to the number of books which attempt to explain the spirit and aims of modern mathematics to the intelligent layman.

The Greeks began the search for a discipline which should be abstract and general, but Prof. Meschkowski takes a long stride from Greek mathematics to the next significant stage, the discovery, early in the nineteenth century, of the plurality of geometries by Gauss, Lobachevski and the Bolyais. Curiously, he scarcely notices the sequential but equally important work of Grassmann, Hamilton and Boole, on the plurality of algebras—so seminal for modern formalist developments. The antinomies and paradoxes of Cantor's theory of sets, and Brouwer's dismissal of the law of the excluded middle, lead to problems of mathematical logic, which Prof. Meschkowski approaches from the geometrical side by a study of Hilbert's axiomatic construction. The formalism which dominates so much of present-day thinking about mathematics demands discussion of the consistency and completeness of an axiomatic system, and presents the 'undecidable' problems of mathematical logic, with Gödel's proof that the consistency of the formal number system cannot be established by means of the system alone, and Skolem's theorem that a finite system of axioms cannot uniquely characterize the set of natural numbers. The account of this rugged domain is as clear as we could hope for; many readers will appreciate the quotation from André Weil: "God exists since mathematics is consistent, and the Devil exists since we cannot prove it".

A further chapter on operative mathematics, based on papers by P. Lorenzen, will prove a severe test of the sophistication of even the most intelligent layman. In an appendix, the author suggests that there are educational possibilities in modern mathematics which were only latent in the classical nineteenth century developments, and that these could be made to lead to a new unity in our educational system. He remarks that the liberal arts might be better served if students in technical institutes, instead of being compelled to attend lectures on literature, were encouraged to reflect seriously on the fundamentals of their own subjects. Thus they would be led to see that poets, philosophers and scientists may indeed all have the same goal.

T. A. A. BROADBENT

RADIONUCLIDE FRACTIONATION IN AIR-BURST DEBRIS

By Dr. E. C. FREILING and M. A. KAY

U.S. Naval Radiological Defense Laboratory, San Francisco, California

WHEN one considers world-wide fall-out, air bursts are of much greater significance than surface bursts for two reasons. First, because a much greater quantity of fission products has been produced by air bursts than by surface detonations and, secondly, because the entire amount of debris from an air burst goes into world-wide fall-out, as compared with some small but unknown fraction for a surface burst.

Although a large amount of information has been collected on air-burst debris, relatively little has appeared in the unclassified literature. A few remarks on the nature of air-burst debris are therefore in order by way of background. The particles from air bursts are almost exclusively spherical, although occasionally particles are found which consist of two spheres stuck together. The particles are small, rarely occurring larger than 20μ in diameter. Lapple has estimated that these particles can only grow to 0·3μ by condensation and are probably no smaller than 0·03μ (ref. 1). Therefore either the larger particles must have been formed by the coalescence of small particles when the debris was still in the molten state, or they were formed from debris which was never completely vaporized. In either case they probably consist predominantly of particles formed at the earlier times. The size-frequency distribution has been measured down to 0·05μ diameter and found to be approximately lognormal with a modal diameter less than 1μ (ref. 2). The densities of the particles vary from 3 to 4·3 g/c.c. (ref. 3). They may be colourless, gold, yellow, orange, red, brown, green or black. Their chemical composition is usually a mixture of the oxides of iron, aluminium, uranium and plutonium. Radiochemically, their specific activity is much greater than that found in surface burst debris, as would be expected. Thus, while the more active particles from surface bursts contain of the order of 10^{14} ^{95}Zr-equivalent fissions per gram*, air burst particles may have specific activities from 10^4 to 10^7 times higher. Benson *et al.* have recently determined that in larger particles from air burst debris ^{95}Zr content varies as the 3·1–3·4 power of the diameter, while ^{140}Ba–^{140}La content varies as the 2·3–2·6 power (ref. 4).

Most of the samples investigated have shown a relatively small degree of fractionation. However, since most samples were collected with precautions to obtain as representative a collection as possible, one should not leap to the conclusion that air-burst debris is fractionated to only a small extent. A large number of samples have also been obtained which showed large departures from the representative composition. The analytical data from these samples provide a wealth of material for analysing fractionation in air-burst debris.

It is helpful to draw a distinction between potential and actual fractionation when considering the extent to which air-burst debris is fractionated. By 'potentially fractionated debris' we mean debris for which the radiochemical composition varies among particles, whether because of their size, density, macroscopic composition or history in the fireball, even though these particles are intimately mixed so as to provide a representative composition for any given cubic foot of cloud. For example, the work of Benson *et al.* already cited (ref. 4) clearly shows that the debris from an air burst is potentially fractionated, even though the debris taken as a whole is obviously representative. In order to actualize this potentiality, a particle separation process must occur. If the separation is the result of unequal rates of sedimentation through the atmosphere, the process could extend over long periods of time, and the degree of actualization would increase as time went on.

The correlation of radiochemical data from fractionated samples of air-burst debris throws light on the fundamental nature of the processes involved in debris formation: the nuclear processes of the primary fission products; the dispersion and subsequent nucleation, condensation and agglomeration of the carrier material; the incorporation of the primary fission products in the particle or their deposition on the particle surface. The correlative parameters show the influence of matrix material on the character of the fractionation and provide input data for prediction schemes, such as the radial-distribution model[6]. A search of available radiochemical data on air-burst debris revealed thirteen detonations in which factors of ten or more were observed between the same radionuclide ratios in different samples from the same detonation. Two additional shots were included to extend the range of weapon yields. These detonations ranged in total yield over a factor of about 300. All the radiochemical data available from these fifteen detonations were used in this work. For each of these detonations, the investigators in charge of the analyses had estimated representative (that is, unfractionated) values of the radionuclide ratios obtained. Therefore, the ratios of fractionated radionuclides were converted to fractionation ratios ($r_{i,j}$) by simply dividing them by the representative values, as described in ref. 6.

Standard statistical methods were used to analyse the correlations between ratios, to test the variation of the correlation parameters with total weapon yield, and to test the hypotheses that nuclides of certain groups do not fractionate from one another.

To illustrate the range of fractionation observed in air-burst debris, Table 1 lists for each shot the ratio of the largest $r_{89,95}$ value observed to the smallest $r_{89,95}$ value observed. The shot numbers are assigned in order of increasing yield. The data show that air-burst debris can be extremely fractionated. There is no evident trend of the ratio with yield. The wide variation in the ratio probably manifests nothing more than its dependence on the sampling conditions. The observed $r_{89,95}$ values ranged from 0·002 to 5·3, although few fell outside the range of 0·1–3·0.

The next property considered was the relative ability of logarithmic and linear correlations to fit the data. The measure used for goodness-of-fit was the coefficient of determination (that is, the square of the coefficient of

* In any given event, an equivalent fission of a fission product or induced activity is the ratio of the total quantity of product to the total number of fissions and thus represents the average quantity of product formed by one fission.

correlation)[7]. These coefficients indicate the fraction of variance in the dependent variable accounted for by the best fit of the type indicated. Individual shots varied considerably and were about equally divided in their preference. Table 2 shows the cumulative coefficients (that is, coefficients obtained from treating all the data from all shots as belonging to a single population) for several important radionuclides which fractionate from ^{95}Zr to varying degrees. With the single exception of ^{141}Ce, which shows no significant difference, the cumulative coefficients indicate a preference for the logarithmic correlations. Unfortunately, this preference is influenced to some unknown extent by the type of scatter in the data. Data which have about the same 'relative' uncertainty (as these do) will tend to follow a logarithmic correlation, while data which have about the same 'absolute' uncertainty will tend to follow a linear correlation[8].

Table 2. CUMULATIVE COEFFICIENTS OF DETERMINATION FOR IMPORTANT FRACTIONATION-SENSITIVE NUCLIDES

Radionuclide	Coefficient of determination: Logarithmic fit	Linear fit
^{90}Sr	0 71	0·51
^{91}Y	0·85	0·60
^{137}Cs	0 69	0·60
^{140}Ba	(0·76)*	(0 65)*
^{141}Ce	0·71	0·72
^{147}Nd	0·37	0·05
^{239}Np	0·78	0·64

* Slopes are yield dependent.

The yield dependence of the slopes of the logarithmic correlation lines were calculated for the nuclides ^{90}Sr, ^{91}Y, ^{97}Zr, ^{99}Mo, ^{137}Cs, ^{140}Ba, ^{141}Ce, ^{147}Nd and ^{239}Np. This was done for both total device yield W and for log W. In most cases the regression slope for this dependence was equal to or less than the 95 per cent confidence limit. The results for those cases where the regression slopes exceeded the confidence limits are shown in Table 3. The ^{140}Ba slopes definitely appear to be dependent on yield, the dependence is in the expected direction, and the slopes themselves varied from 0·41 to 0·92. The ^{99}Mo slopes also appear to be dependent on yield. These ranged from 0·10 to 0·59. The cases for the other nuclides appear much less definite.

Table 3. REGRESSION SLOPES FOR STATISTICALLY SIGNIFICANT CASES OF YIELD DEPENDENCE

Radionuclide	Correlation with W (kt^{-1})	Correlation with Log w
^{91}Y	0·00016 ± 0·00015	———*
^{99}Mo	0 00019 ± 0 00011	0 066 ± 0 039
^{140}Ba	0·00016 ± 0 00009	0·053 ± 0 035
^{141}Ce	0 00011 ± 0 00007	———*
^{147}Nd	−0 00013 ± 0 00010	———*

* Slopes did not exceed confidence limits.

We come now to the values of the regression slopes for logarithmic correlations of the data from all shots treated as a single population. Because of our basis of presentation, these slopes are measures of the volatility of behaviour of the various mass chains. The cumulative slopes for the logarithmic correlations, their 95 per cent confidence limits, and the number of data points involved, are shown for various important radionuclides in Table 4. Nuclides are listed in order of decreasing volatility (decreasing slope) for air bursts. Although not strictly admissible, because of yield dependence, ^{99}Mo and ^{140}Ba have been included to indicate typical values for these cases. Listed for comparison are the cumulative results from high-yield surface bursts which have been taken from ref. 6 and converted to the present basis (that is, ratios are here based on ^{95}Zr instead of ^{89}Sr).

Table 4 CUMULATIVE SLOPES FOR VARIOUS IMPORTANT RADIONUCLIDES

Radionuclide	No. of data points	Cumulative slope	High-yield surface bursts
^{89}Sr	by definition	1·000	1·000
^{90}Sr	209	0·92 ± 0 08	0 69 ∓ 0 08
^{137}Cs	190	0·90 ± 0·09	1·07 ± 0 17

^{143}Pr		188	−0·10 ± 0·03
^{161}Tb	^{95}Zr	156	0 04 ± 0·05
^{153}Sm		159	0·03 ± 0 05
^{156}Eu		175	0 00 ± 0 05
^{97}Zr		239	−0 03 ± 0 03

The simplified picture of fall-out formation has visualized a yield-dependent time of condensation or solidification of debris, at which refractory elements were largely incorporated in the particle matrix while volatile elements had either to cool further or to decay to refractory elements before they could condense on the available surfaces. Some of the results in the preceding section are unexpected from such a model, but it cannot be universally stated whether this disagreement lies with the fault of the model, of the basic nuclear data and its application, or in the accuracy and treatment of the radiochemical data. Each anomaly must be treated individually, compared with other correlations, and the relative contribution of all four possible causes evaluated.

The insensitivity of correlation parameters to yield, in all cases except ^{99}Mo and ^{140}Ba, simplifies the prediction of debris properties but is difficult to reconcile with the simplified model described here. Equally difficult to explain on a physical basis is why these particular nuclides should show the greatest yield dependence. Plots of correlation parameter versus yield show a great deal of scatter and the results here may simply reflect a larger number of data points (compare Table 4) and more

reliable results for these nuclides, rather than signifying a real insensitivity for the others.

The observed volatility of ^{239}Np, on the other hand, appears more real. Besides the magnitude of the volatility, the results are well supported by independent data. Thus, ^{239}Np, ^{237}U and ^{240}U are all present as uranium at condensation time and, as Table 5 shows, the data from these three nuclides are all in excellent agreement. Moreover, a similar, though less marked, behaviour has been reported for the silicate surface bursts Small Boy and Johnie Boy in ref. 9.

In using Table 5 to determine whether two nuclides do not fractionate from each other, the slope, confidence limits, and the chemical and nuclear properties of the precursors must all be considered. The following groups of nuclides fulfil well all these qualifications: ^{237}U, ^{239}Np and ^{240}U; ^{111}Ag and ^{115}Cd; ^{95}Zr and ^{97}Zr; and ^{153}Sm, ^{156}Eu and ^{161}Tb. The data also indicate that there is no reason for excluding ^{112}Ag from the silver group, that the silver group does not fractionate sensibly from the uranium group and that the zirconium group does not fractionate from the heavy rare earth group. As would be expected, ^{136}Cs and ^{140}Ba behave very similarly. The volatile nuclides ^{89}Sr, ^{90}Sr and ^{137}Cs may also follow one another in air-burst debris and ^{115m}Cd may follow ^{115}Cd, but the indication that they do is marginal, to say the least. The data of Tables 4 and 5 indicate that ^{143}Pr is more volatilely behaving than the heavy rare earths and that ^{147}Nd behaves more volatilely than ^{143}Pr. The confidence limits for ^{144}Ce are too wide to establish its position among the other rare earths.

Fig. 1 presents a visual comparison of the chain volatility inferred from fractionation behaviour with the parent thermodynamic volatility shown by Fig. 2 of ref. 10. In the latter, Bedford and Jackson show the predominant form of the condensed phase and its equivalent pressure at 2,500° K and 1 atm. O_2 for the fission-product elements and uranium. The correspondence between the two sets of data indicates that the thermodynamic equilibrium model for nuclear debris formation proposed by Miller[11] may be applicable to air bursts and this possibility should be investigated further.

Some of the results here were compared with those for silicate surface bursts in ref. 9. The comparison with results from high-yield surface bursts in Table 4 shows ^{239}Np to be the nuclide the behaviour of which differs most in these environments. The difference between the values for the 140 chain in the two cases is well within the 95 per cent confidence limits as is the difference between values for the 137 chain. Discussion of the differences for ^{90}Sr and ^{99}Mo are best postponed until work in progress on additional correlations from high-yield surface bursts in the Pacific area is complete.

In conclusion, it is evident that our understanding of the situations prevailing in the formation of air-burst debris is rudimentary in all phases: the basic theory is lacking; the models are crude and it is somewhat surprising that they work as well as they do; fundamental thermodynamic and nuclear data are unavailable; the environmental conditions during debris formation are inadequately defined; the particles are formed and grow and coagulate at different times, places and temperatures, the larger ones being probably the first formed; and the subtlety of some of the effects sought appears to be beyond the accuracy of the data and the methods of correlation. For these reasons, no more detailed treatment has appeared to be warranted at this time. As correlation data accumulate from other burst types, as fundamental data become available, and as basic processes are better understood, more sophisticated statistical treatment and interpretation may prove fruitful.

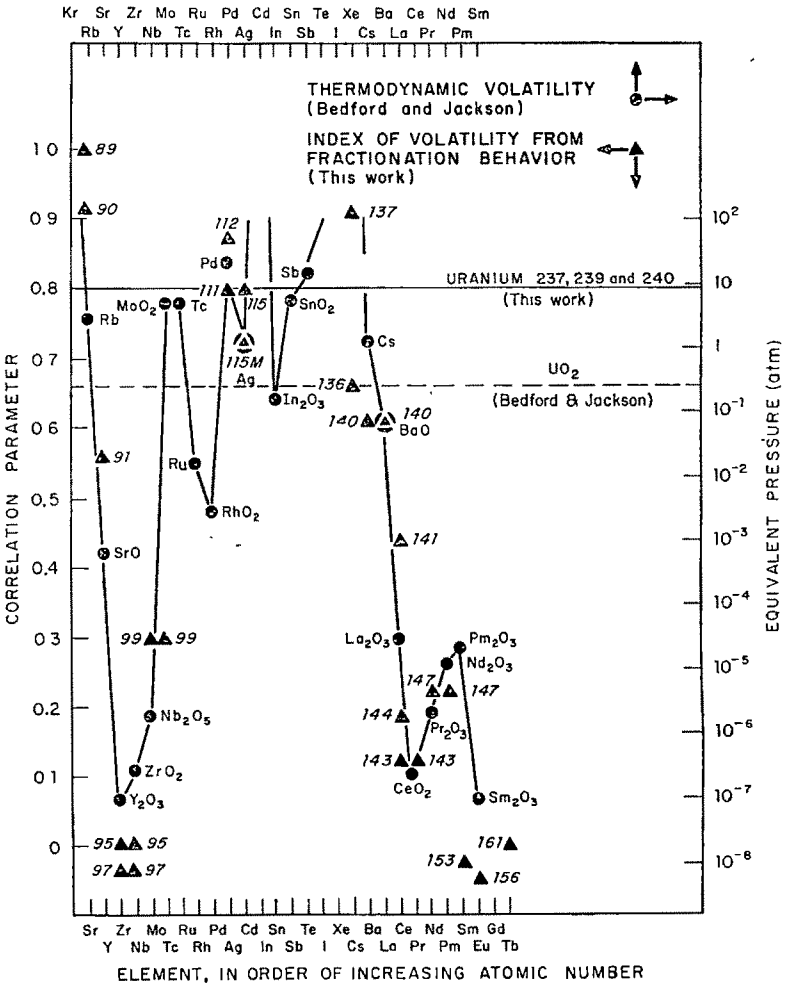

Fig. 1. A comparison of chain volatility inferred from fractionation behaviour with thermodynamic volatility of the parent

We are grateful to the U.S. Atomic Energy Commission for support of this work. The data were obtained from U.S. Air Force sources. Messrs. R. L. Ottinger and D. A. Monheit assisted in various phases of the work.

HIGHLY FRACTIONATED NUCLEAR DEBRIS RESULTING FROM THE VENTING OF A SOVIET UNDERGROUND NUCLEAR TEST

By Prof. SEITARO KOYAMA, Dr. TAKESHI SOTOBAYASHI and TOSHIO SUZUKI
Department of Chemistry, Faculty of Science, Niigata University, Niigata, Japan

THREE months after the first Chinese atomic bomb test the U.S.S.R. conducted a large-scale underground nuclear test on January 15, 1965, at Semipalatinsk in central Asia. The total yield of this explosion was roughly estimated to be 0·1–1·0 megaton of TNT. The high radioactivity was detected in rain-water collected at Niigata on January 21. The total β-activity of the rain sample decreased with an apparent half-life of 23 days, whereas the total γ-activity of the rain sample indicated an apparent half-life of 13 days, as shown in Fig. 2. It was reported by Murayama *et al.*[1] that Wakkanai (Fig. 1) was also subject to radioactive rainfall on January 21 and 22, and that the apparent half-lives of total β-activity of the rain samples were about 27 days, similar to the Niigata rain sample. On the other hand, highly radioactive dry fall-outs were observed at Fukuoka, Osaka and Sapporo meteorological observatories (Fig. 1) during the period of January 21–23, where no rainfall occurred[1]. Their apparent half-lives of total β-activity were all 15 days, shorter than that of the Niigata rain sample. Such a long apparent half-life of total fission-product β-activity has not previously been observed within a week of explosion, from the point of view of fresh nuclear debris from an atmospheric or ground-level nuclear weapon testing.

From the γ-ray scintillation spectra for the Niigata rain sample, it will be seen that the principal γ-emitting nuclide was barium-140 (–lanthanum-140) and that the peak at 0·23 MeV showed the presence of a small fraction of tellurium-132 (–iodine-132), relevant to an underground nuclear test. The γ-ray spectra, however, indicated no separate peak at 0·36 MeV of iodine-131—perhaps one of the most interesting fission products resulting from an underground test[2]. This lack of iodine-131 in the γ-ray spectra may be explained by the differences in the following mass-131 and mass-132 fission-product decay chains:

$$^{131}\mathrm{Sn}(3{\cdot}4\ \mathrm{min}) \rightarrow {}^{131}\mathrm{Sb}(23\ \mathrm{min}) \begin{cases} \xrightarrow{5\%} {}^{131m}\mathrm{Te}(30\ \mathrm{h}) \\ \xrightarrow{95\%} {}^{131}\mathrm{Te}(25\ \mathrm{min}) \end{cases} \rightarrow {}^{131}\mathrm{I}(8\ \mathrm{day})$$

$$^{132}\mathrm{Sn}(2{\cdot}2\ \mathrm{min}) \rightarrow {}^{132}\mathrm{Sb}(2{\cdot}1\ \mathrm{min}) \rightarrow {}^{132}\mathrm{Te}(78\ \mathrm{h}) \rightarrow {}^{132}\mathrm{I}(2{\cdot}3\ \mathrm{h})$$

That is, the selective deposition of fission products from an underground nuclear test is greatly affected by their physical and radiological properties, including those of their precursors. The half-lives of tin-131 and tin-132 are comparable with each other and hence the activities of both nuclides decrease with a similar rate. The half-life of antimony-131 is more than ten times longer than that of antimony-132. Consequently, when only a half of the antimony-131 is converted into tellurium-131, the conversion of antimony-132 into tellurium-132 is almost entirely completed. The boiling-point of elemental antimony (1,380°) is higher than that of elemental tellurium (990°), and, in addition, the specific activity of tellurium-132 is a few times larger than that of iodine-131. From such radiological properties of these nuclides and, further, the distance from Semipalatinsk to Niigata (5,000 km), it can be plausibly explained that the peak of iodine-131 was not identified in the γ-ray spectra of the rain sample. However, it seems reasonable to associate

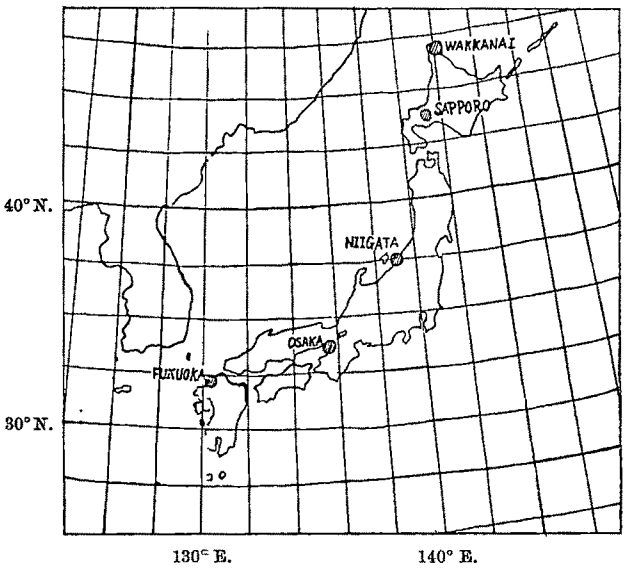

Fig. 1. Locations where wet or dry fall-out from the Soviet underground test was observed during January 21–23, 1965

the source of such a highly radioactive rain or dry fall-out with an accidental venting of the large Soviet underground test.

As the testing date and site of this test explosion are clearly known, the debris is of interest as it demonstrates the radiochemical composition of nuclear debris from a distant underground test and the duration of atmospheric contamination caused by such a test.

A rain-water sample collected on January 21 (sample volume, 6·0 l.) was submitted to radiochemical analysis, and the results are summarized in Table 1. The 'measured' values are shown by the activity contribution from each nuclide on January 30, 1965. The 'expected' values are also given by the contribution to be expected 15 days after the fission of uranium-235 by means of slow neutrons. The first striking feature of the results shown in Table 1 is that nuclear debris from the underground test indicated the occurrence of high fractionation during escape, transport or deposition, as demonstrated above by γ-ray spectrometry. The main components of the rain-water sample were strontium-89 and barium-140 (–lanthanum-140) and they represented 95 per cent of the total activity on January 30, 15 days after the explosion. The contribution from the remaining components, such as tellurium-132 (–iodine-132), ruthenium-103 (–rhodium-103) and rare earths, made up only 5 per cent of the total

Table 1. Radiochemical Composition of Rain-water Sample collected on January 21, 1965

Nuclides	Contribution to total activity (per cent) 'Measured' on January 30, 1965	'Expected' 15 days after fission
Strontium-89	60	4
Strontium-90	0·6	0·03
Barium-140	16	12
Lanthanum-140	18	14
Caesium-137	0·2	0·03
Remainder	5	70

activity. It is considered that the selective release of strontium-89 and barium-140 into the atmosphere results from the fact that their precursors in the fission-product decay chains include inert gas elements, such as krypton and xenon, which have a half-life of more or less than 1 min. Nuclides with very short-lived precursors were not enriched in fall-out samples, although their precursors were inert gas elements. From this selective enrichment of some nuclides it is possibly to be expected that the contribution from strontium-90 and caesium-137 exceeded, by a factor of 10, that calculated in the case of thermal neutron fission of uranium-235. The ratio of caesium-137 to strontium-90 was 0·5 and less than one-third of an averaged value of the ratios which have been reported by other investigators in Japan[3,4]. It should be noted that the debris from the underground test was enriched with strontium-90 in great excess as compared with caesium-137.

A decay curve of the mixture sample plotted on semi-logarithmic paper is shown in Fig. 2. This assumes an artificial mixture sample containing strontium-89 and barium-140 (–lanthanum-140) with an activity ratio, strontium-89/(barium-140+lanthanum-140), of 60/34 on January 30. From this graph it was assessed that the total β-activity of the mixture sample had an apparent half-life of 24 days during the period January 21–February 10: its half-life was in good agreement with that of our rain-water sample of January 21. This agreement suggests that the rain samples collected at Wakkanai would also consist mainly of strontium-89 and barium-140 (–lanthanum-140).

The activity concentration of strontium-89 and the ratio of strontium-89 to strontium-90 during January 21–24 are presented in Table 2, together with their average values for the period January 21–31. All activity values in Table 2 have been corrected for radioactive decay to mid-period of the collection. For the first half of January the average activity concentration of strontium-89 due to the first Chinese test had been reduced, on the average, to the very low level of about 1 pc./l. The rain on January 21, however, showed the surprisingly high activity concentration of strontium-89 of 9,970 pc./l. Afterwards the activity concentration decreased rapidly, and on January 24 it was but a fiftieth of its value of January 21. The atomic and activity ratios of barium-140 to strontium-89 are also listed in Table 2, together with the fractionation coefficient. The fractionation coefficient is equal to the measured barium-140/strontium-89 ratio divided by the calculated barium-140/strontium-89 ratio for uranium-235 thermal neutron fission. The activity ratio of barium-140/strontium-89 was only 0·46 on January 21, and the ratio rose abruptly to 4·66 in the afternoon of January 22; however, its mean value over the period January 21–31 was 2·12 because the individual values were averaged by pooling individual samples for 10-day periods. The strontium-89 activity was substantially enriched in the first sample collected. The barium-140 activity clearly indicated a reverse trend of the enrichment. However, the average value of the fractionation coefficient was about 1 for the period January 21–31. From the results described here, it seems probable that the radioactive cloud of strontium-89-rich nuclear debris, which escaped from the underground test, was carried on an easterly course,

Table 2. Concentration of Strontium-89, Strontium-89/-90, and Barium-140/Strontium-89

Period of collection January, 1965	Sample volume (l.)	^{89}Sr concentration (pc./l.)	Ratio $^{89}Sr/^{90}Sr$	$^{140}Ba/^{89}Sr$ Atomic	$^{140}Ba/^{89}Sr$ Activity	Fractionation coeff.
1400, 21–1800, 21	5 8	9,970	100	0·13	0·46	0·2
1800, 21–1200, 22	21·0	2,480	98	0·70	2·72	1·0
1200, 22–1800, 22	19·0	430	71	1·20	4·66	1·7
1800, 22–900, 23	20 5	372	48			
1000, 24–1400, 24	19 5	195	20			
21–31	46·0	378	34	0·55	2·12	0·9

at the level of the rain-forming layers, and reached Japan within 5 days; moreover, in transit the strontium-89 was scavenged by the rain clouds. On the other hand, it is reasonable to assume that the cloud of barium-140-rich nuclear debris travelled towards Japan along a low-level course in the troposphere and that the cloud was brought down near the Earth surface by descending air flows associated with surface anticyclone.

Table 3. Atmospheric Mean Time of Residence of Strontium-89 produced by the Underground Test

Period of collection January, 1965	Composite removal constant ($\lambda r + \lambda_{Sr\text{-}89}$) By ^{89}Sr concentration	By ratio $^{89}Sr/^{90}Sr$	Mean time of residence From concentration	From ratio
1400, 21–1200, 22	2·48		(0·4)	
1800, 21–1800, 22	2·48	0·67	(0·4)	1·5
1200, 22–0900, 23	0·79	0·41	1·3	2·5
1800, 23–1400, 24	0·65	0·81	1·5	1·2
		Average	1·4±0·1	1·7±0·5

From the ratio of two consecutive values of strontium-89 concentration, the nominal composite removal constant ($\lambda r + \lambda_{Sr\text{-}89}$) and the mean residence time of strontium-89 in the lowest troposphere were estimated on the assumption that removal of strontium-89 activity from the atmosphere was an exponential function. The results obtained are presented in Table 3, where λr is the nominal removal constant for the depletion process of strontium-89. The composite removal constant, which is listed in the column designated as 'by ratio', was also determined by means of two consecutive values of the ratio (Sr-89/Sr-90) in the same way as by the strontium-89 concentration. In this case, the strontium-89/strontium-90 ratio is regarded as the 'amount of deposition of strontium-89 activity' corrected for an additional increase arising from the meteorological conditions. The mean time of residence of strontium-89 in the lowest troposphere, below the rain-forming layer, was estimated by the two different methods to be, on the average, 1·5 days. This value may suggest a measure of the duration of atmospheric contamination with downwind fall-out due to a distant underground test. It can be stated that the substantial air contamination with the fission-product activity continued for less than a week.

SYMPTOMS AS AN INDEX OF BIOLOGICAL BEHAVIOUR AND PROGNOSIS IN HUMAN CANCER

By Prof. ALVAN R. FEINSTEIN

Departments of Medicine and Clinical Biostatistics, Yale University School of Medicine, New Haven, and VA Hospital, West Haven, Connecticut

MOST concepts of the biological behaviour of human cancer depend on the morphology of the tumour. The evidence obtained by physical, surgical, roentgenographic and microscopic examination is used to identify the site, size, cellular type, regional invasion and distant dissemination of the tumour. These identifications then form the basis for decisions about rates of growth, prognosis and treatment for the cancers of individual patients.

From these morphological assessments, physicians have evolved the therapeutic concept that a cancer is most curable when discovered early and removed completely. In this concept, a tumour is 'early' if found before it has invaded any important regional structures or spread to distant sites; and the tumour is removed 'completely' if its anatomical situation permits excision of all the visible lesion together with a wide margin of normal tissue.

These morphological principles of therapy have been repeatedly confirmed by the many cases in which prompt surgical resection has cured a patient of his or her cancer. Yet the rule has also been violated by many exceptions. Some patients have died quickly despite a prompt and apparently 'complete' excision of a cancer discovered 'early'. Other patients have had long survival with cancers that were not removed either because the patient refused operation, or because the surgeon decided not to attempt resection.

An explanation for this capricious behaviour of cancer has been proposed in a hypothesis called "biologic predeterminism"[1]. According to this hypothesis, tumours with similar morphological appearance may nevertheless grow differently, and those with favourable biological growth are those most likely to be discovered 'early' in a state suitable for surgical cure. Although this hypothesis provides an attractive explanation for the observed discrepancies in behaviour of cancer, verification of the hypothesis has been difficult because of inadequate methods for identifying 'favourable' features of growth of the tumour.

Perhaps the main reason for the inadequacy of existing methods is that they identify form without identifying function. The conventional morphological data describe the appearance of the tumour and the structural damage it has produced. But morphology does not provide direct evidence of the functional effects of the tumour on structures or systems that are not anatomically invaded, nor does the morphological appearance indicate how long the tumour has been present. The term 'early', used so often in discussions of cancer therapy, is generally applied inappropriately. Although 'early' refers to a dimension in time, the usual evidence assessed in the designation of 'early' comes mainly from anatomy, not chronometry. The evidence depends on size, lymph nodes and metastatic dissemination, not on the length of time the tumour has been present.

Additional evidence of the functional and temporal growth of a tumour is available in the symptoms the tumour produces in its human host. Yet symptoms are seldom formally analysed or correlated in the therapeutic evaluation of human cancers. Although regularly noted in diagnostic decisions, and in the informal reasoning of 'clinical judgment', symptoms are usually not specifically cited, categorized, and analysed in the evaluations of prognosis and therapy. One main reason for the neglect of symptoms has been their variability. Because patients with the same morphological properties may have different symptoms, physicians have often concluded that symptoms are too psychically subjective to merit scientific consideration. A second reason for ignoring symptoms has been their lack of a taxonomy. No formal system of classification has been available for dividing symptomatic patients into sub-groups whose categories are consistent and reproducible.

The purpose of this article is to demonstrate that symptoms can be classified, that variations in symptoms often represent functional variations in the tumour rather than mere psychic reactions of the host, and that symptoms are an important index of biological behaviour, prognosis, and therapy of human cancers. The concepts will be illustrated by data obtained from surveys of large numbers of patients with cancers of the lung and of the rectum.

METHODS

(I) Classification of Symptoms

A disease (or pathological lesion) either does or does not produce symptoms in its human host, and the symptomatic host either reacts or does not react to the symptoms by seeking medical attention. These clinical humanistic aspects of a disease are the basis for classifying symptoms in a recently described system of clinical taxonomy[2,3]. The basic features of classification are the types of symptoms and the manner in which the diseased patient came to clinical detection.

A cancer can produce three main types of symptoms:

(*a*) *Primary symptoms.* These symptoms can be attributed to the tumour at its primary locus or to inflammation surrounding the tumour; none of the symptoms *per se* implies dissemination of the tumour. For example, in cancer of the lung, the primary symptoms would be: a recent cough; haemoptysis; chills, fever or sweats of an associated pneumonia; recent dyspnoea; or appropriate types of chest pain. In cancer of the rectum, the primary symptoms would be: bleeding; a significant recent change in stool appearance or in bowel habits; ano-rectal discomfort; or appropriate types of abdominal pain.

(*b*) *Systemic symptoms.* These symptoms arise as systemic effects remote from the primary site of the tumour, but the systemic symptom does not *per se* imply that the tumour has spread beyond that primary site. For example, anorexia, significant loss in weight and fatigue are systemic symptoms in cancer of either lung or rectum. The joint pains of hypertrophic pulmonary osteoarthropathy are systemic symptoms in cancer of the lung.

(*c*) *Metastatic symptoms.* These symptoms imply *per se* that the cancer has spread beyond its primary locus. For example, in cancer of the lung, invasion of the mediastinum is implied by dysphagia, by hoarseness due to a non-moving vocal cord, or by the manifestations of the superior vena cava syndrome; dissemination of tumour beyond the thorax is implied by bone pain, by cutaneous nodules, or by neurological manifestations. In cancer of

the rectum, metastatic symptoms would be bone pain, ascites, jaundice, or an unequivocally enlarged, nodular, hard liver.

(2) Attribution of Symptoms

Two main problems in the categorization of symptoms arise from decisions about the sources of symptoms. The first problem is the decision whether a particular symptom is due to the tumour or to some other disease that may co-exist in the same patient. For example, if a patient has both chronic emphysema and a cancer of the lung, should his recent dyspnoea be attributed to the emphysema, to the cancer, or to both? Our classification policy in these situations has been to attribute a symptom to the cancer when the symptom could not clearly be attributed to some other disease. For example, the symptom of visual difficulty in a patient with cancer might have been caused by an ocular or cerebral metastasis of the cancer. These neoplastic causes of visual difficulty could be excluded, however, if the patient had a cataract or some other local condition that was clearly the cause of the ocular symptoms. In making these 'attribution' decisions, we ascribed a symptom to some other cause if the other disease existed and seemed unequivocally responsible for the symptom. If a symptom could not be clearly excluded as definitely due to some cause other than the cancer, we included and classified that symptom among those attributable to the cancer.

A second type of problem is the decision whether certain symptoms attributable to the cancer should be regarded as primary or metastatic. For example, the symptomatic entity of pleuritic chest pain could arise from inflammation of pleura in a pneumonia secondary to the obstruction by the tumour of its primary bronchial site. Alternatively, the symptom might be due to neoplastic invasion of muscle, bone or pleura. In these situations, the symptoms are due to the cancer, and the problem is one of classification, rather than attribution. Any reasonable policy of categorization can be applied, so long as it is used consistently. Our policy has been to use the term 'metastatic', as defined earlier, for symptoms that were unequivocally associated with metastasis. When the symptom did not *per se* indicate metastasis, it was arbitrarily assigned to the 'primary' category for these analyses. In more detailed analyses to be reported elsewhere at a later date, such symptoms have been further sub-divided according to the concomitant presence or absence of morphological evidence of metastasis.

(3) Spectral Combination of Symptoms

Of all the symptoms present in a particular patient, certain symptoms can thus be noted as attributable (or possibly attributable) to the cancer. Of those attributable (or possibly attributable) to the cancer, some symptoms will be classified as primary, some as systemic and others as metastatic.

At the time a patient is first discovered to have a cancer, he may have none, one, two or all three types of these symptoms. Because the symptoms can occur alone, or in various combinations, the Venn diagrams of symbolic logic and set theory are a convenient way of illustrating the different components of the symptomatic spectrum. In the population of patients with a cancer, the seven possible types of sub-sets with different combinations of symptoms are shown in the Venn diagram of Fig. 1, which represents the complete clinical spectrum of a diagnosed cancer. An additional sub-set is provided by the patients whose tumour is discovered by accident while the patient is still asymptomatic. The circumstances in which such asymptomatic accidental discoveries occur have been described elsewhere[2,3]. (The remainder of the 'universe' of cancer of the lung, beyond these eight sub-sets, contains patients in whom the disease is present but not diagnostically detected.)

(4) Prognostic Implications of Symptomatic Stages

Of the eight sub-sets of patients just described, the four with metastatic symptoms (sub-sets 5–8) have a manifestly poor prognosis, because the presence of the metastatic symptoms indicates anatomic spread of the tumour beyond the primary site. In the remaining four sub-sets—who have no metastatic symptoms—the presence of systemic symptoms in sub-sets 3 and 4 suggests a situation less favourable than in the patients of sub-sets 1 and 2, who have neither metastatic nor systemic symptoms.

In sub-sets 1 and 2, whose symptoms *per se* have no unfavourable morphological or functional connotations, the duration of the symptoms can next be considered. For patients with primary symptoms only (sub-set 2), the duration of symptoms indicates a minimal time for the duration of the tumour—since the tumour has been present at least as long as its symptoms. If the symptoms are of short duration, no conclusion can be drawn about the rate of growth of the tumour. The symptoms may be short because the tumour has grown rapidly, or the tumour might have grown slowly with an eventual 'iceberg effect' in which symptoms did not appear until quite late in the course of the tumour. If the symptoms are of long duration, however, the tumour is likely to be slow-growing. The only way a patient could continue to have primary symptoms only, for a long time, without developing systemic or metastatic symptoms, would be to have a slow-growing tumour.

In the asymptomatic patients of sub-set 1, whose disease is discovered by accident during an examination performed routinely or for a complaint unrelated to the cancer, the duration of symptoms cannot be assessed since no symptoms exist. In such patients, the tumour has been present for unknown lengths of time and might have remained symptomatically silent for even longer lengths had the tumour not been accidentally discovered.

With these considerations, the eight sub-sets of Fig. 1 can be rearranged to create five main symptomatic groups or stages. In the new arrangement, which is shown in Fig. 2, sub-set 1 remains intact as the 'asymptomatic' group (Stage I). Sub-set 2 has been divided into two parts, according to whether the duration of symptoms was less than 6 months or at least 6 months: the 'long primary' group (Stage II) contains patients with primary symptoms only, of duration 6 months or more; and the 'short primary' group (Stage III) contains patients with primary symptoms only, of duration less than 6 months. Sub-sets 3 and 4 have been combined to form the systemic group (Stage IV), and sub-sets 5, 6, 7 and 8 have been combined to form the 'metastatic' group (Stage V).

From the foregoing discussion and from the hypothesis of "biologic predeterminism", we can anticipate a prognostic gradient among these five symptomatic states. The survival rates should be best in Stages I and II,

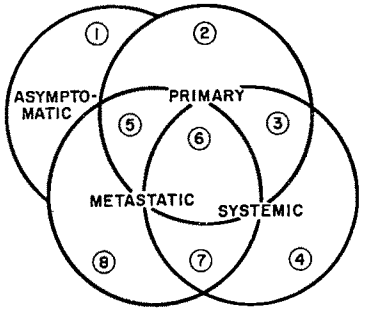

Fig 1. The clinical spectrum of a diagnosed cancer. This Venn diagram shows the 'intersections' of sets of patients with primary, systemic, or metastatic symptoms, occurring alone or in the various illustrated combinations. The asymptomatic group—with none of these symptoms—is distinguished from the remainder of the 'universe' of patients whose cancer has not been diagnosed. The eight sub-groups (or sub-sets) are further described in the text

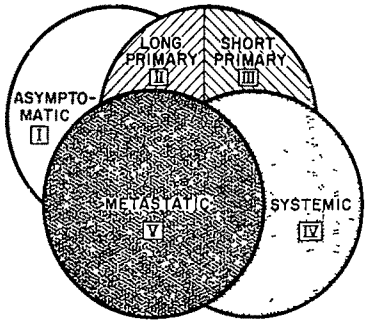

Fig. 2. Symptomatic stages of a cancer. The eight sub-sets of Fig. 1 are combined or divided to form the five mutually exclusive symptomatic stages shown here. For further details, see text

declining through Stages III and IV to the worst results in Stage V. Yet these prognostic distinctions—particularly in Stages I–IV—would not be discernible from morphological data, and could be detected only from analysis of symptoms.

(5) Selection of Patients and Methods of Survey

The medical record files of both the Yale–New Haven and West Haven Veterans Administration Hospitals were searched for the names of all patients who had received the diagnosis of primary cancer of the lung or of the rectum during the years 1953–58. The latter boundary was selected to ensure at least a 5-year follow-up period for the survey, which began in 1963; the opening year coincided with the opening of the VA Hospital. The survey was restricted to patients in whom histological proof of the cancer had been obtained during life or after death. Patients with cancer of the lung had had various cellular types of tumour; in cancer of the rectum, the type was exclusively adenocarcinoma. Records of the individual patients were then reviewed by methods described elsewhere[4,5].

For each patient, a complete chronology of the neoplastic illness was constructed, including all details pertinent to its earliest manifestations and extending for at least 5 years beyond the index date. For this chronology, additional data were obtained as needed from the Yale–New Haven Tumor Registry and from communication with patients, relatives, physicians and other hospitals. These investigations provided a complete description of the entire subsequent course, for at least 5 years beyond the index date, for each patient in this survey.

The index date selected as a common 'zero time' for all patients was the date of the first treatment. The 'zero time' served as the point at which the clinical state of each patient was classified, and from which the antecedent duration of symptoms and other manifestations, and the subsequent duration of survival, could be measured. Treatment was defined as surgery originally intended to remove the primary tumour (regardless of whether the tumour was actually removed), or radiotherapy directed at the primary tumour, or the administration of a cytotoxic chemotherapeutic agent. Patients who received only analgesics, sedatives, antibiotics or therapeutic measures other than one or more of the procedures just cited were regarded as having received no treatment. For such patients, 'zero time' was the date on which the physician (or patient) had decided against specific anti-neoplastic therapy. In patients who died before any therapeutic decision could be made, 'zero time' was the date of diagnosis.

RESULTS

(1) Overall Survival

Fig. 3 shows the 5-year survival rates for all patients in this survey, regardless of mode of therapy. In the 596 patients with lung cancer, the total 5-year survival was 9 per cent, but the rates ranged from 32 per cent in symptomatic Stage I to 18 per cent in II, 10 per cent in III, 8 per cent in IV, and 0·6 per cent in V. In the 201 patients with cancer of the rectum, the total 5-year survival was 27 per cent, with rates in the different symptomatic sub-groups ranging downward from 67 per cent in Stage I, to 49 per cent in II, 29 per cent in III, 16 per cent in IV, and 0 per cent in V. Thus, the prognostic gradient anticipated from symptomatic considerations was clearly evident in patients with two different cancers. In each cancer, the survival rates were highest in Stage I and became progressively lower to a nadir in Stage V. The distinctions among patients in Stages I–IV are particularly important, since the metastatic aspects of patients in Stage V are usually evident morphologically as well as symptomatically, but the differences among Stages I–IV can be discerned only from symptoms.

For simplicity in the subsequent statistical analyses presented here, we have combined the results of Stages I and II, and of Stages III and IV, thus reducing to two categories the four symptomatic sub-groups of Stages I–IV. With these consolidations, the survival rate in cancer of the lung was 22 per cent (28/127) for Stages I and II and 9 per cent (27/300) for Stages III and IV [$\chi^2 = 12{\cdot}4$; $P < 0{\cdot}001$]. In a similar comparison for the combined symptomatic sub-groups of cancer of the rectum, the rates are 50 per cent (31/62) in Stages I and II as compared with 19 per cent (24/124) in Stages III and IV [$\chi^2 = 17{\cdot}2$; $P < 0{\cdot}001$]. Both differences are highly significant statistically.

(2) Five-year Survival after Surgical Resection

Table 1 shows the five-year survival rates for patients whose tumours were surgically resected. The patients are classified according to the conventional notation of regional lymph node involvement, and are simultaneously categorized by symptomatic stages. The prognostic gradient previously noted for Stages I and II compared with Stages III and IV is still significantly present after surgery. The 5-year survival rate in these two symptomatic categories after resection of lung cancer was 37 per cent compared with 22 per cent [$\chi^2 = 4{\cdot}6$; $P < 0{\cdot}05$]; for rectal cancer, the corresponding data were 55 per cent compared with 28 per cent [$\chi^2 = 9{\cdot}3$; $P < 0{\cdot}01$].

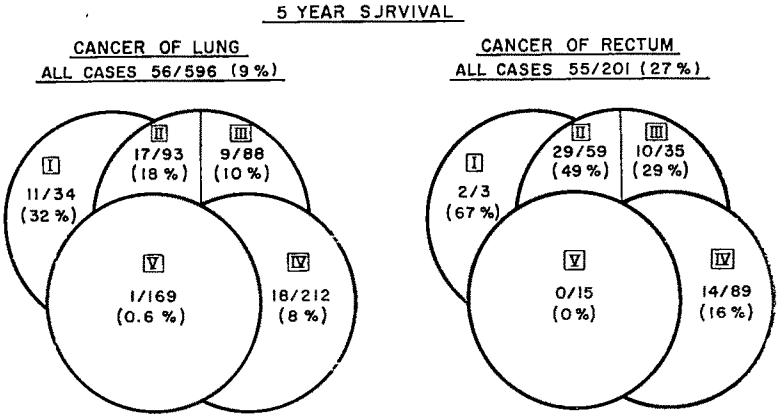

Fig. 3. Five-year survival, regardless of therapy, for the symptomatic sub-groups shown in Fig 2. Denominators represent the number of patients initially in each symptomatic stage, and numerators are the number who survived 5 years or more after therapeutic decisions Although the rates for cancer of the rectum are consistently higher than those for cancer of the lung, the same descending prognostic gradient is present from symptomatic Stages I–V for both cancers

As expected, the patients without neoplastic involvement of regional lymph nodes had better results than those whose nodes contained tumour. In the total results for cancer of the rectum, the patients with 'negative nodes' had a survival rate of 51 per cent, compared with 19 per cent in those with 'positive nodes'. This difference is statistically significant at $P < 0{\cdot}001$ [$\chi^2 = 15{\cdot}0$]. The corresponding values in lung cancer were 31 per cent and 22 per cent—a difference of uncertain significance [$\chi^2 = 1{\cdot}9$; $P > 0{\cdot}2$'.

In each of the two lymph node categories for each of the two tumours, the patients in symptomatic Stages I and II had better survival results than those in Stages III and IV. Although most of the numerical values in these sub-categories are too small for statistical significance, a significant distinction is present in the group with rectal cancer and 'negative nodes'. In patients of this morphological category, the 5-year survival was 68 per cent in symptomatic Stages I and II, and 40 per cent in Stages III and IV. This difference is significant at $P < 0{\cdot}05$ [$\chi^2 = 5{\cdot}2$].

(3) 5-year Survival and Cellular Type in Lung Cancer

All the rectal cancers in this survey were adenocarcinomata. The cancers of the lung, however, had various cellular types. Table 2 shows the 5-year survival rates according to the symptomatic stage and cytological differentiation of the tumours. As expected, the survival rates were better in well-differentiated than in not-well-differentiated tumours. For the total series, regardless of therapy, the cellular distinction in survival rate was 14 per cent compared with 4 per cent—a highly significant difference [$\chi^2 = 17{\cdot}1$; $P < 0{\cdot}001$]. Within the same cytological categories, however, patients in Stages I and II had higher survival rates than those in Stages III and IV. In the well-differentiated group, the two comparative percentages—29 per cent and 13 per cent—were significantly distinct at $P < 0{\cdot}01$ [$\chi^2 = 8{\cdot}5$].

In patients whose tumours were surgically resected, the survival rate for the well-differentiated tumours, 29 per cent, was not significantly higher than the 20 per cent found with undifferentiated tumours [$\chi^2 = 1{\cdot}0$; $P > 0{\cdot}3$]. Yet, in each cellular category, the results of patients in Stages I and II were similar, and higher than those of patients in Stages III and IV. The differences in post-operative survival between these two symptomatic categories—regardless of cellular type—were previously noted in Table 1 to be statistically significant at $P < 0{\cdot}05$. Consequently, as a harbinger of post-operative prognosis in cancer of the lung, the symptomatic stage distinctions were more significant than the cytological appearance of the tumours, and also, as noted earlier, than the invasion or non-invasion of lymph nodes.

Table 1. Five-year Survival after Surgical Resection of Cancers of Lung or Rectum

Symptomatic stages	Cancer of lung* Regional lymph nodes negative for tumour	Regional lymph nodes positive for tumour	Total	Cancer of rectum* Regional lymph nodes negative for tumour	Regional lymph nodes positive for tumour	Total
I and II; (asymptomatic and long primary)	21/51 (41)	7/24 (29)	28/75 (37)	23/34 (68)	7/21 (33)	30/55 (55)
III and IV; (short primary and systemic)	15/60 (25)	11/58 (19)	26/118 (22)	19/48 (40)	5/39 (13)	24/87 (28)
V; (metastatic)	0/4 (0)	1/6 (17)	1/10 (10)	—	0/4 (0)	0/4 (0)
Total	36/115 (31)	19/88 (22)	55/203 (27)	42/82 (51)	12/64 (19)	54/146 (37)

* Values in parentheses are percentages.

Table 2. Five-year Survival and Cellular Type of Cancer of Lung

Symptomatic stages	All types of therapy* Well-differentiated	Not well-differentiated	After surgical resection* Well-differentiated	Not well-differentiated
I and II; (asymptomatic and long primary)	23/79 (29)	5/48 (10)	23/59 (39)	5/16 (31)

* Values in parentheses are percentages.

DISCUSSION

These results confirm the expectations of traditional clinical logic that have not previously been possible to demonstrate because the symptomatic components of clinical reasoning had not been given a formal structure that would permit quantified analysis. With the aid of Venn diagrams, the identified symptomatic ingredients can be arranged into a distinctive and suitable 'taxonomy'.

It is apparent from the data that symptoms indicate aspects of the function and rate of growth of a cancer that cannot be discerned morphologically. Conversely, the morphological properties of a cancer denote anatomical features of growth that cannot be discerned from symptomatology. To understand the biological behaviour of a tumour, and to appraise its prognosis and therapy effectively, both the morphological and symptomatical features must be appropriately classified and analysed.

That patients with a long duration of symptoms often have a paradoxically good prognosis, despite 'late' treatment, has been repetitively noted in many therapeutic surveys of cancer. Among the most recent reports have been the results cited for Hodgkin's disease and for cancer of the stomach[6–8]. Although the existence of a good prognosis for many such patients prompted MacDonald[1] to form his hypothesis of "biologic predeterminism", the hypothesis has seldom been adequately tested and has hitherto remained generally unconfirmed. In many surveys, the significance of the duration of certain distinctive symptoms has been obliterated because the investigators calculated duration as an average for all types of symptoms, instead of restricting the delineation to patients with primary symptoms only. In other investigations the data demonstrating paradoxically good prognosis for many patients discovered after a long 'delay' were usually dismissed as isolated peculiarities of the behaviour of cancer and man, and the biological significance of the data was not further considered.

A patient's decision to seek medical attention is obviously prompted by many different features of man or of disease. Different people, developing the same types of symptoms, will respond to those symptoms in diverse ways. Some people will seek medical attention promptly; others may wait. Nevertheless, few people will long ignore symptoms that are rapidly progressive, frightening, severe or incapacitating. On the other hand, many patients may not rapidly seek medical help when the early primary symptoms of the tumour are neither inconveniencing, dramatic, nor debilitating. Since slowly growing tumours produce symptoms slowly, such patients are often not motivated to visit a doctor until later in the illness when more significant symptoms have developed. In this way, many 'favourable' tumours are not detected until a long duration of symptoms has elapsed. If the tumour is discovered by accident before it has produced any symptoms, it has an even greater likelihood of being slow-growing.

This morphologic-functional interaction of tumour and host in human cancer has several other important implications:

(1) In selecting treatment for individual patients, physicians should not rely on morphology alone. A slow-growing tumour may be resectable for 'cure' even though it invades lymph nodes and is attached to contiguous structures. In many patients of the series surveyed here such tumours, left unresected because these features

made the tumours seem 'inoperable', eventually caused death not by subsequent widespread metastases but by their effects as 'foreign bodies' in the chest or abdomen. Death often resulted from a lung abscess that developed behind the intact tumour, from uraemia due to the compression of ureters by the tumour, or from massive haemorrhage as the tumour later invaded a blood vessel. Conversely, other patients with tumours that were clearly of rapid and unfavourable progression were subjected to fruitless operations and other therapy that increased the agony of the illness without affecting survival.

(2) In the design of therapeutic trials, the clinical population should be stratified according to symptomatic as well as morphological stages. Otherwise the base populations will not be reproducible, and the results will contain inconsistencies that will add to controversy and dilemma in statistics of cancer therapy[8]. Suppose, for example, that two treatments *A* and *B* are equally ineffective, but that treatment *A* is given to a population consisting predominantly of patients from symptomatic Stages I and II, while the population receiving treatment *B* consists mainly of patients from symptomatic Stages III and IV. If the patients have not been stratified for these symptomatic distinctions, the investigators will be unaware of these deceptive differences in two groups of patients that seem the same because they are morphologically similar. When treatment *A* is followed by results that are significantly better than those of treatment *B*, the difference may be erroneously ascribed to the treatment instead of to the disease.

(3) In the research at present devoted to the aetiology and pathogenesis of cancer, investigators may apply many biochemical, immunological, chromosomal and other tests to human neoplastic tissue. The results may show a wide range of variation that appears to have no particular correlation with the morphology of the tumour. Yet, if the neoplasms were categorized by function as well as by form, many of the apparent 'discrepancies' might be explained. Laboratory research at present dismissed as valueless might actually provide important new revelations if the neoplasms were more clearly and specifically defined for correlation.

The complexity of man increases the difficulty of studying human disease, but also enables a diseased man to talk. His description of his symptoms gives crucial information about function of the diseased structures under investigation.

This work was supported in part by a grant, *CA*07155, from the National Cancer Institute. I thank Joyce A. Pritchett, Helen L. Bidwell, Carol R. Schimpff, Lorraine MacI. Phillips and H. Teresa Hatch for technical assistance. Dr. Edgar W. Hull collaborated in obtaining some of the data dealing with cancer of the rectum. I also thank all the physicians, hospitals, tumour registries and medical record librarians who provided additional data to help complete the chronological information about many of the patients under survey.

NEWS and VIEWS

Charles-Leopold Mayer Prize: Dame Honor Fell, F.R.S.

DAME HONOR FELL, director of the Strangeways Research Laboratory, Cambridge, has been awarded the Charles-Leopold Mayer Prize (valued at 100,000 francs) by the Academie des Sciences de l'Institut de France for her contributions to cell biology. These range from experimental embryological studies on limb bone rudiments to the analysis of the mechanism of action of vitamin A and other compounds on cell components and, in particular, the lysosomal apparatus. Dame Honor has been director of the Strangeways Research Laboratory since 1929. In 1964 she received the honorary degree of doctor of science from the University of Oxford and from Harvard University; she was elected a foreign member of the Royal Netherlands Academy of Science, and an honorary Fellow of Somerville College, Oxford. She is also an honorary doctor of science of Smith College, Massachusetts, an honorary LL.D. of Edinburgh, and a Fellow of Girton College, Cambridge.

Deputy Director and Keeper of the Herbarium and Library of the Royal Botanic Gardens, Kew: Dr. C. E. Hubbard, C.B.E.

DR. C. E. HUBBARD retired on November 30 from the post of keeper of the Herbarium and Library and deputy director of the Royal Botanic Gardens, Kew. Dr. Hubbard was born in 1900 at Appleton, Norfolk, and in 1916 started work in the Royal Gardens at Sandringham where, except for a spell in the Royal Air Force during 1918–19, he remained until he joined the Gardens staff at Kew in April 1920. He entered the Herbarium as a temporary technical assistant in 1923 and soon afterwards, under the guidance of Dr. O. Stapf, he started to specialize on the grasses (*Gramineae*), on which family he later became a leading world authority. In 1924 he made a plant-collecting journey in southern and central Spain with the late Rev. E. Ellman, and in 1930 he spent a year in Australia studying grasses and travelling extensively in Queensland, where he made important botanical collections. In 1954 he was awarded the O.B.E. for his outstanding work on the classification of grasses. On October 1, 1957, he succeeded the late Dr. W. B. Turrill as keeper of the Herbarium and Library and assumed the additional responsibility of the deputy directorship of Kew in 1959. In 1960 he was awarded an honorary doctorate of science by the University of Reading. He was advanced to C.B.E. in 1965. Dr. Hubbard's first major published contribution to the study of *Gramineae* was Part 5 of Volume 9 of the *Flora of Tropical Africa* (1930), written jointly with Dr. O. Stapf, including such difficult genera as *Setaria* and *Pennisetum*. In 1937 he alone wrote Part 1 of Volume 10. He contributed the treatment of the grasses to both editions of Dr. J. Hutchinson's *Flowering Plants* (1934, 1959). He also contributed the key to the tribes and genera in Hutchinson and Dalziel's *Flora of West Tropical Africa* (1936). In 1954 his *Grasses*, an admirably illustrated pocket-book dealing with those species occurring in Britain, was published by Penguin Books. In addition, he wrote numerous shorter papers, and many of them were published in the *Kew Bulletin*, including no less than twenty-eight in the series entitled "Notes on African Grasses". Dr. Hubbard's advice on the identification and classification of grasses has been sought by botanists and agriculturalists in many parts of the world, and his specialized knowledge of grasses has also enabled him to give useful service on the Advisory Committee for Research on Sea Defence.

Mr. J. P. M. Brenan

Dr. Hubbard has been succeeded as deputy director and keeper of the Herbarium and Library by Mr. J. P. M. Brenan. Mr. Brenan was born at Chislehurst, Kent. He was educated at Tonbridge School and Brasenose College, Oxford, where he gained first-class honours in the Final Honour School of Natural Science (Botany) in 1940, later becoming M.A. He worked as a departmental demonstrator and then as a University demonstrator in the Imperial Forestry Institute. During 1947–48 he travelled in Northern Rhodesia and Tanganyika, studying their woody plants, and was also a member of the Cambridge Botanical Expedition to Nigeria and the Cameroons, under the leadership of Prof. P. W. Richards. He joined the staff of the Herbarium at the Royal Botanic Gardens, Kew, in 1958, working in the tropical African section, of which he was in charge from 1959 to 1965. In 1954 he was awarded a B.Sc. by the University of Oxford for work on the plant-geography of tropical Africa. In 1965 he was elected botanical secretary of the Linnean Society of London. Mr. Brenan has specialized on the flora of tropical Africa, especially the families *Leguminosae*, *Commelinaceae*, *Sterculiaceae* and *Chenopodiaceae*. His first major work was, in conjunction with Dr. P. J. Greenway, *Check Lists of the Forest Trees and Shrubs of the British Empire, No. 5, Part 2, Tanganyika Territory* (1949). He was responsible, with help from collaborators, for elaborating the plants collected by the Vernay Nyasaland Expedition of 1946 (published in the *Memoirs of the New York Botanical Garden*, 1953–54). He has contributed various families to the *Flora of Tropical East Africa*, including *Leguminosae* Subfamily *Mimosoideae* (1959). He has also written numerous shorter papers on the flora of Africa, and also some on the flora of Britain. Mr. Brenan translated into English Prof. P. Jaeger's book *Le Vie Étrange des Fleurs*, published in 1961 as *The Wonderful Life of Flowers*.

Director of the Tropical Products Institute, London: Mr. E. S. Hiscocks, C.B.E.

Mr. E. S. Hiscocks, director of the Tropical Products Institute of the Ministry of Overseas Development, will retire from the public service on March 31, 1966. After studying chemistry in the University of Wales, where he worked with J. A. V. Butler on physico-chemical properties of solutions, Mr. Hiscocks joined the Civil Service in 1926 in the then Department of the Government Chemist and for several years collaborated with Sir Robert Robertson and Sir John Fox in researches on infra-red absorption spectra of gases and the preliminary work on the structure of diamond. He later did work on ultra-violet absorption spectra of organic compounds and, after serving in various of the revenue sections of the Department, transferred in 1939 to the Raw Materials Department, Ministry of Supply. Here he set up, and ran, the technical branch of that Department. In 1944 he was appointed secretary of the National Physical Laboratory and remained there until 1957, when he became director of the United Kingdom Scientific Mission (North America) and Scientific Attaché to the British Embassy, Washington, D.C. He returned from the United States at the end of 1960 on his appointment as director of the Tropical Products Institute. During his period at the National Physical Laboratory he was closely concerned with the adjustment of the Laboratory's organization and work to the requirements of the post-war period. During this time he wrote numerous papers on various aspects of the organization and administration of scientific work. He also organized an international symposium on the direction of research establishments, held at the Laboratory in 1956. In that year his book *Laboratory Administration* was published. During the five years he has spent at the Tropical Products Institute, Mr. Hiscocks has been concerned not only with reorganization of the Institute's work, to meet the changed requirements of the developing countries of the Commonwealth, but also in extending its scope of operation to other developing countries in the Middle East, South America and the Pacific, during visits to those areas. He has also furthered collaboration between the Institute and various agencies of the United Nations Organisation. Mr. Hiscocks was a United Kingdom delegate to the Pacific Science Congress in 1961 and was United Kingdom delegate to the United Nations Committee for Industrial Development in 1964.

Dr. P. C. Spensley

Mr. E. S. Hiscocks will be succeeded as director of the Tropical Products Institute by the present deputy director, Dr. P. C. Spensley. Dr. Spensley was a foundation scholar of St. Paul's School and of Keble College, Oxford, where he studied chemistry. His research after the Second World War in the Dyson Perrins Laboratory at Oxford was mainly concerned with the synthesis of organic compounds of possible therapeutic interest. Between 1940 and 1945, Dr. Spensley was on the staff of the Ministry of Supply, Royal Ordnance Factories, where he was concerned with explosives and ammunition production, smoke weapons development and standards. In 1950 Dr. Spensley joined the staff of the National Institute for Medical Research and, in the course of a working visit to East Africa, discovered a method by which a valuable, but minor, component of the sisal plant—hecogenin—could be extracted economically as a by-product of the sisal fibre industry. This process he developed further with the National Research Development Corporation and it is now operated commercially in Tanzania and Kenya to provide hecogenin for the production of steroid drugs. Dr. Spensley received a major inventor's award for this work in 1963. In 1954, Dr. Spensley was appointed to the scientific staff of the Colonial Office in the Imperial Institute and became Scientific Secretary of the Colonial Products Council. With the then director he was closely concerned with the planning which led to the evolution in 1958 of the Tropical Products Institute and soon afterwards he was made assistant director in charge of administration and development. In this post he has travelled widely and attended a number of international meetings. He assisted Sir William Slater in the organization of the British contribution to the major United Nations Conference on the Application of Science and Technology for the benefit of the Less Developed Areas, held in Geneva in 1963.

Plant Pathology in Queen's University, Belfast: Prof. A. E. Muskett, O.B.E.

Prof. A. E. Muskett retired on December 31, 1965, from his chair in the Department of Mycology and Plant Pathology at Queen's University, Belfast, and from his position as head of the Plant Pathology Division of the Ministry of Agriculture for Northern Ireland. A native of Norfolk, he graduated from the Imperial College of Science and Technology, where he studied under Sir John Farmer, and went to Belfast in 1923 on his appointment as a research assistant in the Seed Testing and Plant Disease Division of the Ministry and as an assistant in agricultural botany at Queen's. He obtained his D.Sc. from London in 1938. His continued successes and promotion led to the formation in 1938 of a separate Plant Pathology Division of the Ministry, of which he became head, and led, in 1945, to his appointment to the newly created chair in the University. He was president of the British Mycological Society in 1948. In 1957 he was awarded the O.B.E. Prof. Muskett's early publications on the control of American gooseberry mildew and apple scab led to the adoption of regular spraying programmes suitable for local conditions. The toxicity of lime sulphur sprays to apple trees and the efficiency of an excess-lime Bordeaux mixture were demonstrated. Further research naturally centred chiefly around the potato, oat and flax crops, with special reference to tuber disinfection with organic mer-

curials and to seed disinfection with organo-mercury and thiram-based chemicals. The value of thiram as a satisfactory dressing for flax seed was first shown in 1939 and was a most timely discovery, as it was used on all flax seed saved in the United Kingdom during the Second World War. Following his work on the epidemiology and control of the *Helminthosporium* disease of oats, Prof. Muskett led research in the development of techniques for the examination of seeds for the presence of seed-borne fungi, work which formed a basis for the investigation of biological techniques for the evaluation of fungicides. He also devoted much time to the health of the seed potato crop of Northern Ireland, special facilities being available for work on virus diseases at the Plant Pathology Field Station, erected in 1954. In 1947 he published, with Prof. J. Colhoun, *The Diseases of the Flax Plant*, and in 1964 Dr. J. P. Malone and he published *Seed-borne Fungi*, two books which quickly found a wide circulation. Prof. Muskett was not only an enthusiastic and inspiring lecturer, an energetic administrator during his term as Dean in 1950–57, a useful member of the Academic Council and University Committees and an apt adviser on plant pathology problems, but also a friend and counsellor to many students and members of staff who sought his advice and now wish him a happy retirement.

University Grants

In a written answer in the House of Commons on December 20, the Secretary of State for Education and Science, Mr. A. Crosland, stated that the Government was reviewing the quinquennial system of recurrent grants to the universities. In view of the difficulties which arose because of the fact that under the present system the universities did not know their recurrent grants for the new quinquennium until near the end of the last year of the old quinquennium, the Government, after consulting the University Grants Committee, had decided to make a provisional allocation of recurrent grant for the first year of the next quinquennium (1967–68) well in advance of the final settlement for the quinquennium as a whole. He hoped to be able to announce this allocation towards the end of 1966 and the University Grants Committee had assured him that this change in procedure would be acceptable to the universities. In a written answer on December 22, Mr. Crosland announced that he was authorizing, for starting in 1966–67, a university building programme (in terms of existing cost figures) of £40 million; for 1967–68, £30 million; for 1968–69, £25 million; and for 1969–70, £25 million. He hoped that in future this could be made a rolling programme. The programme allowed a higher level of building starts in 1966–67 and 1967–68 than that at present sanctioned, and it took account of deferment from the present year of some £15 million starts following the Government's measures of July 1965.

Welsh College of Advanced Technology

Mr. Crosland also announced in the House of Commons on December 20 that, after considering the advice of the University Grants Committee, the Government had concluded that it could not support the establishment of the Welsh College of Advanced Technology as a separate degree-giving university. The invitation which the College had received from the University of Wales to become a full constituent member of the University offered an alternative road to university status and the Government was confident that such an arrangement would contribute to the development of the College as a centre of higher technological education. It also believed that the idea of an association between the College, University College, Cardiff, and the Welsh National School of Medicine could well be worked out within the framework of the University of Wales. He understood that the University would shortly be petitioning for the amendments to its Charter necessary to deal with problems arising from its federal constitution.

South-east England : Water Resources

In reply to questions in the House of Commons on December 20, the Minister of Land and Natural Resources, Mr. Willey, said that he hoped to have the advice of the Water Resources Board on the consultant's report on the water resources of the Great Ouse Basin fairly early in 1966, and would then consider the next steps. He would certainly consult the East Anglian Regional Economic Planning Council before putting a feasibility study on the Wash barrage in hand. The Minister of Housing and Local Government had received the report of the consulting engineers, Messrs. Binnie and Partners, on the water resources of the Great Ouse Basin. This report recommended further study of a number of possible conservation schemes, including the use of the Wash as a reservoir. The Water Resources Board had been asked to consider the report in the context of their studies of the South-East as a whole and to advise in due course what action should be taken. The situation was being considered as expeditiously as possible but the advice of the Water Resources Board had first to be awaited.

University of Birmingham—Royal Radar Establishment, Malvern: Working Association

The University of Birmingham has recently concluded an agreement for a working association with the Royal Radar Establishment, Malvern. The agreement, which comes into effect early this year, provides for the co-option of up to six senior scientists from the Royal Radar Establishment on to the University staff; they will have honorary University titles and will spend an average of 1 day a week in the University, taking part in undergraduate and postgraduate teaching, research, departmental policy discussions, and the general life of the University. In the opposite direction, a corresponding number of members of the University staff will be co-opted on to the staff of the Royal Radar Establishment to spend an average of 1 day a week at Malvern, taking part in research and in research policy decisions. The arrangement will not extend to the whole of the Radar Research Establishment, part of which is engaged on work of military importance. On the University side, it will involve the following Departments: Electronic and Electrical Engineering, Electron Physics, Physics (especially solid-state physics), Mathematical Physics, Physical Metallurgy. On the Malvern side the corresponding divisions of the Royal Radar Establishment will be involved.

The Barwell Meteorite

A large meteorite fell at about 16.20 G.M.T. on December 24, 1965, at the village of Barwell in Leicestershire. It is possible that a wider area was involved, as material has now been reported from farther afield, but as yet this has not been examined. The Barwell meteorite has been identified as an olivine bronzite chondrite. So far, 35–40 lb. of this material has been collected, and this is being collated at the British Museum (Natural History). *Bona fide* scientists wishing to investigate material from this meteorite should apply, in the first instance, to Prof. P. C. Silvester Bradley, Department of Geology, University of Leicester.

In-service Training for Science Teachers

Increasing awareness of the need for teachers of science and mathematics to be kept in touch through in-service training (or refresher courses) with modern advances in science moved the Royal Society to hold a conference of representatives of the interests concerned, on September 16, 1965. A report of that conference is now available (The Royal Society. *In-Service Training for School Teachers of Science and Mathematics in England*. Report of

a Conference convened by the Royal Society on 16 September, 1965. Pp. 14. London: The Royal Society, 1965). Prof. H. W. Thompson was in the chair, and in the proceedings sixty-two people took part. The chief conclusions and recommendations which emerged were that a very considerable increase in in-service training for teachers of science and mathematics was urgent. The Department of Education and Science together with Local Education Authorities were urged to provide the necessary financial assistance; in-service training and the development of the science curriculum should go hand in hand; and further links should be established between the learned societies and professional institutes concerned and school teachers of science, to strengthen a sense of community. Those organizations already active in the field should be encouraged to continue, with co-ordination when necessary, perhaps through the Schools Council—in this respect, what was already being done by the Schools Council met with general approval. The recommendations of the Joint Mathematical Council were endorsed. Local Education Authorities, it was felt, should act generously in supporting teachers who wished to attend courses; and the Royal Society should bring the report of the meeting to the attention of a wide range of public bodies, universities and other interested groups. Hesitation about these conclusions came mainly from K. S. Tetlow, representing the teachers' point of view. His enquiries had shown that no teachers were interested in courses of one term's duration or more; there was no enthusiasm for courses held during the holidays; and the pupils would suffer if courses were held during term time. There was, however, a strong desire for more information about modern advances in science, as well as for courses of one or a few days' duration, held at strategic times during the school year.

Registrar General's Quarterly Return

The Registrar General's Quarterly Return for the June quarter of 1965 shows that births in the first two quarters of 1965 were fractionally lower than in the corresponding quarters of the previous year (439,000 as against 449,000) (General Register Office. *The Registrar General's Quarterly Return for England and Wales—Births, Deaths and Marriages; Infectious Diseases; Weather; Population Estimates, Quarter ended 30th June, 1965*. Pp. 40. London: H.M.S.O., 1965. 2*s*. 6*d*.). The seasonally adjusted birth-rate has also fallen slightly. This is the first time during the past ten years that the figures have failed to show an increase, but it is difficult to draw any conclusion from this short period. The infant mortality rates continue to decline, and have fallen by 25 per cent during the past ten years. Marriages tend to be stable in number. The first provisional analysis of death in 1964 by cause, age and sex appears in the *Return*: deaths from lung cancer were 3·5 per cent up on the 1963 figures among men and nearly 6 per cent up among women; the increase in deaths due to motor vehicle accidents was nearly 15 per cent among both sexes. Nearly 45 per cent of the deaths of males aged 15–24 were attributable to this cause. The expectation of life at birth in 1962–64 was 68·1 years for men and 74·2 for women.

Fuels for the Future

"Man's use of energy has progressed from wood and dung to coal and oil, is now taking a large contribution from gas and moving towards uranium, plutonium, and ultimately sea-water." This challenging statement appears towards the end of an entertaining and prophetic article by Keith Richardson entitled "Fuels for the Future" (*Catalyst*, 15; Autumn 1965. London: Shell Chemical Co., Ltd., Plastics and Rubbers and Industrial Chemicals Divisions). Mr. Richardson surveys the present highly competitive fields of coal, oil, electricity and gas; and the future impact of nuclear energy. Of the coal industry, he says that the main trouble is its great inflexibility. The over-riding question is, what is the future of the coal industry in our economic scheme of things? At present, it produces 66 million tons a year from loss-making pits, mainly in Scotland, Wales and the North-East. Arguments in favour of keeping a strategic reserve of coal capacity—pits that can be opened if ever needed—are attractive, but impracticable; once a coal mine is closed it is closed for ever, because of rock-pressure and water flooding; if we are to be able to call on 200 million tons of home-produced coal in the future, that same amount must be bought now to keep the pits in being. Before coal is ever likely 'to get into balance', uneconomic pits must be abandoned. "The tragedy is that business which could profitably be won by Midlands coal at £2 a ton is lost to oil because the price structure is all wrong." It is the oil industry that has damaged coal, but it has also spurred it to greater efficiency. Mr. Richardson considers that the oil supply situation looks as though it will become tougher between 10 and 30 years from now, because costs of exploration and of extraction will rise; oil-bearing countries may grow reluctant to let so much of their resources be shipped to Britain as they now do; this, it is argued, is why the present North Sea explorations are so tremendously important. In the latter context, gas is now better envisaged as an offshoot of the oil industry, because the British Gas Council can make its own gas just as cheaply from oil as from other sources; ". . . as surely as oil has won fuel business from coal, in time it will lose it back to electricity". But the golden future thus predicted for electricity depends neither on coal nor on oil (including gas), but on atomic power. The advanced gas-cooled reactor now offers the cheapest means of generating electricity. By the 1980's fast breeder reactors should produce more fuel than they use. Two other intriguing possibilities for future fuels are briefly discussed in this article: one is the prospect of the fuel cell gradually replacing the petrol and diesel engine; the other is thermonuclear fusion. If the latter is a practicable source, it means power from sea-water "in virtually unlimited quantities". Finally, there is that devastating machine called the 'Thetatron', ". . . which in six-millionths of a second can develop 12 million amps of current, and this has achieved momentary bursts of 10 million degrees". As Mr. Richardson naively says, at least it points the way. This is an extremely able essay into the complex problems of fuels for the future.

Balancing Capacity and Sales

Achieving Balance between Capacity and Sales, a booklet containing papers given at a conference on this theme at Birmingham during May 1965, is now available (Pp. 31. London: British Productivity Council, 1965). The conference was organized by the British Productivity Council, in co-operation with the British Institute of Management, the Centre for Inter-firm Comparison and the Birmingham and Coventry Productivity Associations. The introductory paper, by H. Ingham, director of the Centre for Inter-firm Comparison, stated that there are a few frequently occurring and typical patterns of co-ordination between sales and capacity, each of which can be described as a basic marketing objective with resultant typical opportunities and risks. Companies of a similar type, although making different products, face broadly similar problems of balance, so that a firm can improve its methods of co-ordination by comparing them with those of other firms of its type. The co-ordination outlined in the type descriptions given can be used as 'blueprints'. Ingham also discussed the influences of co-ordination practices on profitability. Three case studies were also presented to show typical major patterns of co-ordination: the first by H. A. Hollingsworth, chief production controller of Wilmot Breeden, Ltd.; the second by J. W. Fewless, director of the Heath Street Division of G.K.N. Screws and Fasteners, Ltd.; and the third by L. A. Williams.

head of the Operational Research Unit of Ferranti, Ltd. (Transformer Division).

Brucellosis

Food and Agriculture Organization Agricultural Studies No. 66 embodies the report of the joint World Health Organization/Food and Agriculture Organization Expert Committee on Brucellosis (Food and Agriculture Organization of the United Nations. *Joint FAO/WHO Expert Committee on Brucellosis—Fourth Report.* Pp. 65. Rome: Food and Agriculture Organization of the United Nations. London: H.M.S.O., 1964. 6*s.* 8*d.*; 1.25 dollars). Its fourteen sections discuss the epidemiology of brucellosis; speciation in the genus *Brucella*; media and methods for the primary isolation and further cultivation of the organism; the standardization and interpretation of the serum agglutination test; human, bovine, caprine and porcine brucellosis and the disease in other animals; the United Nations brucellosis centres and future research needs. Nine annexes deal with various aspects of the immunology of *Brucella* infections.

Engineering Aspects of Lubrication

An intensive course on "Engineering Aspects of Lubrication", organized by Dr. A. Cameron, will be held in the Department of Mechanical Engineering, Imperial College of Science and Technology, during May 31–June 17. The various processes underlying the operation of bearings are often extremely complex and the aim of the course is to enable engineers and industrialists to have a better understanding of them. In this way, they will be better able to design equipment and understand failures. The content of the course will be as follows: First, classical lubrication theory will be developed and compared with the practice of journal and thrust bearings, the importance of temperature being emphasized and a method produced for analysing its effect. The combined influence of pressure on viscosity and deformation of surfaces will then be discussed and the method investigated by which ball and roller bearings and gears are lubricated. The various theories of oil film break-down will be considered and a reasonable theory of scuffing put forward. A number of specialist lectures will be given by recognized experts. Full bound sets of lecture notes will be issued to every student attending the course. Further information can be obtained from the Registrar, Imperial College, London, S.W.7. The fee for the course will be 45 guineas.

Post Office : Postgraduate Awards

The Post Office is arranging to make each year a number of postgraduate awards to selected staff. These awards will be tenable at universities which have facilities for research or advanced studies relevant to Post Office problems, initially in telecommunications science and engineering. In appropriate cases the awards will enable the holders to qualify for M.Sc. or Ph.D. degrees. The primary objective, however, is to further research and develop expertise of special value to the Post Office.

Prof. G. Macdonald, C.M.G. : The Ross Institute, and Schistosomiasis

The Editor has received the following communication from Prof. G. Macdonald: "I am happy to correct the statement on p. 30 of your January 1 issue that I have given up my directorship of the Ross Institute, a post which I retain and hope to enjoy for some years. The Ross Institute, under my direction, has been very interested in schistosomiasis for several years, and in 1961 it received a substantial grant from the Rockefeller Foundation to study the medical and public health significance of this infection, the grant being further supported by the Ministry of Overseas Development and the World Health Organization. With this aid, a Schistosomiasis Research Unit under Dr. Forsyth has been working in East Africa since 1962, originally based on the East African Medical Research Laboratory at Mwanza and now in Zanzibar. The World Health Organization* also sponsors work on this disease, and much research has been carried out by the staff of the Research Laboratory at Mwanza".

*WHO Technical Report Series No. 299 (price 5*s.* from H.M.S.O., P.O. Box 569, London, S.E.1) and *Snail Control in the Prevention of Bilharziasis* (price 30*s.*, from the same address).

University News:

Hull

Dr. R. R. Baldwin has been appointed to the second chair of chemistry as from January 1.

Leeds

Dr. E. Irving has been appointed to a chair of geophysics in the Department of Earth Sciences.

London

The following appointments have been made: *Professorships*, Dr. E. W. Horton (pharmacology, tenable at the School of Pharmacy); Dr. J. T. Stuart (theoretical fluid mechanics, tenable at the Imperial College of Science and Technology); *Readerships*, Dr. B. E. Plunkett (botany, tenable at Birkbeck College); Dr. E. Cohen (mineral technology, tenable at the Imperial College of Science and Technology). The following titles have also been conferred: *Professor*, Dr. J. Joseph (anatomy, in respect of his post at Guy's Hospital Medical School); *Reader*, Dr. T. H. Lambert (mechanical engineering, in respect of his post at University College).

Swansea

Prof. J. A. Beardmore, professor of genetics in the University of Groningen, has been appointed to the newly established chair of genetics.

Announcements

A series of courses on subjects in the field of natural sciences will be held at the Scottish Field Studies Association's Field Centre at Kindrogan, Perthshire, during 1966. Further information can be obtained from the Scottish Field Studies Association, Ltd., 141 Bath Street, Glasgow, C.2.

A general discussion of the Faraday Society on "The Role of the Absorbed State in Heterogeneous Catalysis" will be held in the University of Liverpool during April 4–6. Further information can be obtained from the Assistant Secretary, the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

A meeting of the East Midlands Branch of the Institute of Mathematics and its Applications will be held at Loughborough College of Technology on January 18. A lecture on "The Mathematical Theory of Multi-variable Control Systems" will be delivered by Prof. H. H. Rosenbrock. Further information can be obtained from the Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex.

A series of seminars for senior production executives will be held at the Northampton College of Advanced Technology during the first six months of 1966. Subjects under discussion will be as follows: the implications of economic and technological change for industrial relations (January 19); PERT costing as a tool for higher management control of projects (February 16); financial analysis of projects involving capital expenditure (March 23); optimal replacement decisions: alternative approaches to the replacement of machines (April 20); the effects of organization on budgetary control in a manufacturing enterprise (May 13); operations research as an aid to factory location (June 22). Further information can be obtained from the Secretary, Department of Management and Social Science, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

SCIENCE IN PARLIAMENT

University Accounts

IN moving, on December 7, that the House of Commons take note of the first, second and third reports from the Committee of Public Accounts in the Session 1964–65 and of the Treasury minute on the reports, Mr. Boyd-Carpenter referred, more particularly, to the paragraphs in the reports which related to the denial of access by the Comptroller and Auditor-General to the books of the universities. While the Committee had before it much material in respect of the universities, that material was based mainly on information received from the Department of Education and Science and the University Grants Committee. Mr. Boyd-Carpenter questioned whether, with the increasing scale of public provision for the universities and the changed position of the University Grants Committee, which now came under the Department of Education and Science and not directly under the Treasury, this exclusion could be justified and whether its removal would really involve interference with academic freedom. He pointed out that in recent years the Comptroller and Auditor-General had had access to the books and records of the Colleges of Advanced Technology and of the Scottish central institutions. This access would cease when these institutions attain university status. The Committee of Public Accounts suggested, accordingly, that it might be appropriate to reconsider whether the exemption of this large and growing area of expenditure from accountability to Parliament was still justified. Mr. Boyd-Carpenter merely suggested that the issue should be re-examined with an open-minded and clear realization of the implications and that the universities should have the opportunity to express their views. In this he was supported by Mr. T. Dalyell, who also raised the question of the costs of research, suggesting the appointment, apparently under the University Grants Committee, of a small executive body of scientists, seconded for 2 or 3 years to deal with expenditure on physics, engineering, chemistry and biology on a national basis.

The Financial Secretary to the Treasury, Mr. N. MacDermot, in replying on the debate, welcomed the Committee's proposal to look further into this matter, but emphasized the importance of ensuring that academic freedom was maintained, while we obtained the greatest possible value for money. It did not follow that use of the most up-to-date techniques of control and management involved making the University Grants Committee responsible to Parliament and, without prejudicing the question, he seemed more inclined to accept the advice and recommendation of the Robbins Committee.

Manufacture of Enriched Uranium

In a statement in the House of Commons on December 9, the Minister of Technology, Mr. F. Cousins, said that the Government had decided to modernize and reactivate the Capenhurst plant of the Atomic Energy Authority, so that it might supply enriched uranium for the manufacture of fuel for the second nuclear power programme. Owing to a decrease in the demand for enriched uranium for military purposes, and because the civil demand was then very small, it was decided, in 1962, that production of highly enriched material for military purposes should cease, and that of slightly enriched material for civil use be reduced to the minimum level needed to maintain gaseous diffusion technology. This decision was implemented by the end of 1963. For a nuclear power programme of 8,000 MW by 1975, using the advanced gas-cooled reactor design adopted for the Dungeness '*B*' station, several hundred tons of slightly enriched uranium oxide would be required each year. The Authority had designed modifications to the Capenhurst plant that should greatly increase the efficiency of production and had advised him that the gap between Capenhurst prices and those of the alternative United States source should narrow progressively during the 1970s. Other factors to be taken into account included the obvious disadvantages of complete dependence on an overseas supplier, since nuclear power would meet an increasing proportion of the total demand for electricity. Production in the United Kingdom would save imports costing some millions of pounds, and ultimately some tens of millions of pounds per annum. Closure of Capenhurst would make it impossible for Britain to maintain its expertise in this field, while manufacture in Britain would provide the Authority with opportunities to export slightly enriched uranium fuel.

The Government had approved in principle plans involving a capital expenditure of about £13·5 million, the first phase of which, to be started immediately, would cost about £7·5 million. These plans were expected to meet the initial requirements of the new nuclear power programme, and it was envisaged that the plant could be further expanded as requirements increased, and decisions would be taken as necessary. Work would start immediately and the modernized plant would be in operation in time to supply fuel for the first advanced gas-cooled reactor of the second nuclear power programme, Dungeness '*B*'. Mr. Cousins commented that, at present, the difference between British and American prices for fuel was estimated at 10 per cent, but the electricity costs in diffusion were likely to fall, because electricity in Britain was becoming cheaper. The difference to the ultimate consumer was likely to be about 0·25*d*. in the pound. If Britain were to manufacture low-enriched uranium, and if various types of station were to be built around the world, it was possible that Britain would be in the market to sell to them. The Atomic Energy Authority also had in mind the possibility of supplying tailor-made fuel to tailor-made stations. Centrifuge plant might possibly make present methods obsolete, but it would probably be by the late 1970s before centrifuge plant became a possibility. All the information available at the moment led the Authority to believe that it need not worry about the position for the next 10 years. The method under discussion provided opportunity for a changeover at a later stage, if necessary. Non-industrial staff at Capenhurst at present numbered 455, and industrial staff 860. When the plant was in full production a further 200 industrial workers might be required.

A similar statement was made in the House of Lords by Lord Snow, also on December 9, who, in reply to questions, affirmed that the Government was confident that the supply of enriched uranium could be increased to meet any foreseeable demand.

Social Sciences Research Council

In moving approval of the draft Social Science Research Council Order, 1965, in the House of Lords on November 18, the Parliamentary Secretary to the Ministry of Technology, Lord Snow, said that the Government accepted, in general, the functions and powers proposed by the Heyworth Committee. These were embodied essentially in article 2 (1) of the Charter and in the schedule to the Draft Order, which was drawn up in terms

similar to those appearing in the Charters of other research councils. The Social Science Research Council would be breaking more new ground than the other Research Councils, and its first task would be to decide in detail its own programme of activities and methods of working. It would not, for the time being, set up research units of its own and would probably concentrate initially on supporting research at present being carried out in the universities and elsewhere and on providing a focal point for co-ordinating and disseminating information. One of the problems facing the Council would be to define its own sphere of operations; however, economics, sociology, social psychology, social anthropology and political science would be its immediate concern. The Council would assume some of the functions hitherto performed by the Human Sciences Committee of the Science Research Council and the Department of Education and Science in regard to awards to postgraduate students. Arrangements for discussion with the other bodies concerned would include the appointment of assessors from Government departments, as well as the representation of the Council on inter-departmental committees concerned with research in the social sciences.

While regretting that the Council was not immediately to conduct research of its own, Lord Taylor welcomed the Order and emphasized the importance of the provision and operation of services for common use in social science, urging that the proper place for the Government's Social Survey was under the Social Science Research Council, where it would be available, not only for departmental investigations, but also for non-departmental studies.

In introducing a similar motion in the House of Commons on November 22, the Secretary of State for Education and Science, Mr. A. Crosland, said that the Department now had research projects in this field to the value of about £1 million. Neither the Order nor the Charter mentioned the Heyworth Committee's recommendation for a special board for educational research, but this did not mean that the recommendation had been rejected by the Government. They regarded it as a matter for decision by the Council itself, and, so far as special arrangements for the field of the 'built environment' were concerned, the Minister of Housing and Local Government was enthusiastic about the objective; however, he did not think that the particular form of organization recommended by the Heyworth Committee was the most likely to achieve this objective. Mr. Crosland also said that the Government thought it was too early to decide on the exact relation between the new Council and the Council on Scientific Policy and also for the Government to reach a definite decision about the amount of finance and the number of postgraduate awards. The Council would have the opportunity of making its own recommendations, and it was not proposed to decide on long-term finance until the Government had had the advice of the Council. Mr. Crosland also emphasized the importance of there being more than one source of finance for Social Science Research, and hoped that the establishment of the Council would not mean that there would be less money available for, or less interest in, other sources of funds for such research. It was not the intention of the Government that the work at universities, financed from the University Grants Committee or from other Government departments, should be limited in any way in consequence of the establishment of the Council.

In the debate, Mr. D. Price commented on the greater difficulty of isolating a situation for detailed study in social sciences than in physical sciences. This difficulty of providing or creating controlled conditions in social research meant that the quality of the people conducting such research might be even more important than in the physical and natural sciences. This was one reason why he hoped that the Research Council would give particular attention to the supply of trained research workers. He also emphasized the great importance of inter-disciplinary work, and suggested that the immediate problem was for more research in the nature of 'applied' rather than 'pure' research in this field. Mr. Price considered that this particularly applied in regional development and that industry would get a fairly rapid return from further expenditure in sponsoring applied social science research. Finally, he also urged the appointment of a Select Committee on Science and Technology to examine the reports of other Research Councils, including those of the new ones.

Mr. A. Blenkinsop, agreeing that the quality of research workers in this field was of considerable importance, directed attention to the desirability of such workers having had experience in various fields of the social sciences; these should not be exclusively academic. Mr. R. Hornby hoped that the new Council would be able to stimulate co-operation within the universities, as well as the flow of ideas for projects, and that it would have regard to the needs of other specialized institutions for finance. Mr. G. Howe emphasized the importance of wide and effective dissemination of information on social science generally. Mr. E. S. Heffer referred to the need for more social scientists in local government and in industry and also thought that all colleges of technology should have a department which encouraged the development of the social sciences. Sir Edward Boyle agreed as to the assistance which the Social Science Research Council might give to future Royal Commissions and the wider use which might be made of social science; he emphasized the danger of taking important decisions on inadequate knowledge.

Mr. R. E. Prentice, in replying on the debate for the Government, agreed that effective liaison and communication were basic essentials. The co-ordination of relations between the Council and the work being done in this field in the universities and smaller research institutions was a primary function of the Research Council. The Council had been incorporated by Royal Charter on October 29. The Heyworth Committee's recommendation regarding the Social Survey was being studied by the departments concerned. He also agreed that it was important that Parliament should discuss the work of all the Research Councils and thus help to create an informed public opinion which would facilitate the application of the results of their work.

THE NUFFIELD FOUNDATION

THE report of the Nuffield Foundation for the year ended March 31, 1965*, which includes a tribute to Sir Hector Hetherington, opens by emphasizing once again that the two recurrent themes of the Foundation's work are need and opportunity. The first does not decrease while men remain sensitive to possibilities of knowledge and human benefits, and the second will also be present so long as those who have good ideas and the determination to pursue them will share their thoughts with the Foundation.

Allocations during the year totalled £2,045,741. Of this £205,730 was for biological research and £26,000 for other scientific research; £317,100 was allocated for medical research, £201,065 for social research, and £655,154 for education. Grants for the Commonwealth overseas totalled £182,276 and for fellowship and scholarship schemes, £188,588.

* *The Nuffield Foundation: Report for the year ended 31 March, 1965.* Pp. xlv+161. (London: The Nuffield Foundation, 1965.)

The report expresses concern that the interest of the Foundation in 'food safety' has to some extent failed to communicate the importance and urgent interest of the subject. The Foundation believes that, with the increasing use of additives in food and of chemical and physical procedures in its preparation and storage, there is a corresponding need for more understanding of their biological consequences to ensure that they are not damaging to human health. Too little is known of the long-term biological effects, whether for good or for ill, and it is this programme that is described and delimited by the term 'food safety'.

During November 1964, the Foundation held a one-day conference to examine training needs and possible remedies in the pathology of laboratory animals, and the sum of £2,500 was allocated to meet the cost of a symposium of experts in this subject to be held in April 1966. £250 annually is to be devoted towards the cost of specially arranged lectures in universities on subjects relevant to the Foundation's interest in 'food safety'. A grant of £43,000 over 3 years was made to the Department of Physiology, University of Bristol, mostly towards providing the equipment for recording and analysis of significant features of the apparently random wave-forms of the synaptic activation noise in the control of motoneurones by the brain.

A grant of £9,200 over 3 years was made to the Department of Physiology and Biochemistry, University of Southampton, for research into the trophic factors controlling nerve-muscle functions, and one of up to £8,000 for a pre-fabricated building for ecological research, in the Department of Natural History, University of Aberdeen. A further grant of £10,250, over 2 years, was made to the Department of Anatomy, University College, London, for continued research into the lipid composition of neurones. Other grants for scientific research include a capital grant of £20,000 to strengthen the working scientific fund of the International Council of Scientific Unions and a tapering grant of £6,000 over 3 years, to the Institute of Science Technology, to further its work in the education and training of science laboratory technicians.

The report attributes a decrease in applications and grants in the field of social research to a reluctance to embark on major developments before the Hayworth Committee Report was received. It is anticipated that, in consequence, a more directed approach will now be forthcoming, and emphasis is laid on the importance of drawing more people of ability into the social sciences. Although the Foundation's main concern in this field is a practical contribution to human well-being, it will also support fundamental projects which promise to give form and clarity to the social sciences and to indicate their scope and possible achievements. The Centre for Urban Studies, University College, London, has so far published six reports but it is difficult for the Centre to provide the necessary security for its research staff and carry out the continuing basic work of collecting and analysing data. The Foundation is accordingly making two grants of £20,000 over 2 years in the expectation that, by the start of the new university quinqennium in 1967, funds will be available from public sources for the work of the Centre. A grant of £40,000 was made to the Bartlett School of Architecture, University College, London, for a study of the development of Central London since 1947, and a further grant of £13,000 over 3 years was made to the Department of Architecture, University of Edinburgh, for the continuance of investigations of quantity surveying in the planning of domestic housing. A grant of £14,300 over 3 years was awarded to the Department of Sociology, University of Essex, for measurements of incapacity and disability, in a programme of research into the sociology of handicap, and a grant of £7,500 over the next 3 years was made to the Institute of Commonwealth Studies, University of Oxford, for collecting and sorting records of all kinds from those who have served overseas in former British Colonies. A grant of £23,500 was made to the Institute of Race Relations for its survey of race relations in Britain and a further grant of £30,000 to the National Institute of Economic and Social Research, for the second half of its investigation into the cost of urban redevelopment, which is to be completed by October 1966.

In education, the development of the school curriculum remained a main interest, but the Foundation is now likely to play a diminishing part in sponsoring such work. The School Mathematics Project, which has been assisted by the Foundation over a number of years, has from its start been based on the University of Southampton, and two new projects announced in the report are being sponsored and organized by appropriate university centres, rather than directly by the Foundation; the Trustees are anxious to encourage this trend. Now that the new Schools' Council for the Curriculum and Examinations has taken over the functions of the Secondary Schools' Examination Council and also assumed a national responsibility for stimulating curriculum developments in all subjects at all school levels, the Foundation is likely to turn its attention to other growing-points in education.

Apart from its continuing support for the Foreign Language Teaching Materials Project, the Foundation (in partnership with other organizations) is now sponsoring the work of a national Committee on Research and Development in Modern Languages which will act as a central co-ordinating agency, and a source of stimulus for further advance in this field. Meanwhile a further £528,000 has been set aside for the Science Teaching Project. Three 'O'-Level programmes for the General Certificate of Education in biology, chemistry, and physics were tested in 170 schools in Britain during the academic year 1964–65. Arrangements were made for public examinations to be set at 'O'-Level for pupils from the trial schools in the years up to and including 1967. A new programme was authorized during the year to develop a course for teaching science to non 'O'-Level secondary school children and, to cater for schools which wished to avoid the distinction between physics, chemistry and biology at the beginning of the 5-year 'O'-Level course, a short programme was started to develop a combined science course for the 11–13 age-group. Detailed work on science courses for the sixth form began during the year. In the Mathematics Teaching Project (5–13) a large-scale testing programme commenced in September 1965, with the feeding into the pilot schools of the draft materials for infants and first-year juniors.

A further grant of £13,000 over 3 years was made to the Communications Research Centre, University College, London, for the appointment of four teachers of English with experience at various levels for the English Language Project. A grant of £34,500 over 3 years was made to the Cambridge School Classics Project which is concerned with teaching classics in the initial stages of the school course. A grant of £8,000 was made for a detailed feasibility study of the curriculum needs of the early school-leaver, including a survey of the work at present being carried out in social studies courses for pupils of average and less than average ability. A further allocation of £125,000 until September 1966 was made for the work of the Language Teaching Materials Project in which the Spanish, Russian and German sections now have their own specialist consultative committees.

£100,000 was set aside for programmes recommended by the Committee on Research and Development in Modern Languages formed in September 1964, and sponsored jointly by the Department of Education and Science, the Scottish Education Department, the University Grants Committee, the British Council, the Federation of British Industries and the Foundation. A grant of up to £40,700 over 4 years has been made to the Language Centre, University of Essex, for linguistic analysis of contemporary

Russian, and one of £20,000 over 3 years to the Language Research Centre, Birkbeck College, London, for a scheme of research into applied linguistics and the psychology of language learning. A grant of up to £20,700 over 3 years was made to the Department of Child Life and Health, University of Edinburgh, for investigations of the development of speech in young children. Grants to the new universities include one of £63,000 over 5 years to the University of York toward the development of a Language Teaching Overseas Centre.

Grants for the Commonwealth overseas include a final grant of £15,000 over 6 years to the Plunkett Foundation for Co-operative Studies, for the development of residential training courses for staffs of agricultural co-operative departments and societies in East and West Africa. Further and final support is being given to the Economic Fellowships of the Overseas Development Institutes by a grant of £15,400 over 2 years, and one of £24,000 was made to the Institute of Education, University College of Dar es Salaam, for the building of a Science Centre. A capital grant of £27,600 was made to the University College of East Africa, University College of Makerere Medical School, to build an extension to the medical library, while a grant of £8,250 was made to support, within the Serengeti Research Project, a 3-year study of animal ecology in the Tanganyika National Parks. The Starehe Boys' Centre in Nairobi received a grant of £18,650 to provide a secondary school. A grant of £2,160 over 3 years was made to the University of Melbourne for continuation of investigations of the metabolism and water relations of Australian heath plants. A further grant of £30,000 to the University of the West Indies was partly towards providing guest-house accommodation for postgraduate visitors, and partly for the establishment of a centre for extramural studies in the Leeward and Westward Islands. One of £10,700 was made towards the capital cost of developing the Fields Studies Centre of the University of Malaya, including the provision of accommodation, and one of £25,500 for a 3-year investigation of agricultural marketing in Mauritius.

Awards for the United Kingdom in medicine and dentistry continued unchanged, but the conditions for dental research fellowships were slightly altered to facilitate a wider choice of candidates; one medical research fellowship and two ordinary fellowships were awarded and twenty-four scholarships in tropical medicine. Two scholarships and four bursaries were awarded in biology and four scholarships in sociology. Under schemes for the Commonwealth, overseas travelling fellowships for graduates for one year's study were awarded to scholars from Australia, Ceylon, India, Pakistan and New Zealand. Two of these were in medicine, eight in the natural sciences and six in the humanities and social sciences. Shorter travelling fellowships for six months were awarded to three public officials and two Trade Unionists from Canada, and nine short-term travel grants were made to senior Canadian scholars (two being in the natural sciences, three in the humanities and four in medicine). The travelling fellowship for a Dominion practitioner was last year awarded to Canada; Dominion travelling scholarships were again awarded to two farmers each from Canada, Australia and New Zealand, and one each from Rhodesia, Zambia and Kenya. The Foundation's original grant of £50,000 over 10 years to the Royal Society and Nuffield Foundation Commonwealth Bursary Scheme was renewed for a further and final period of 5 years at the same rate of £5,000 a year and, in 1964, twenty-two awards were made. So far, 330 grants have been made from the Elizabeth Nuffield Educational Fund, fifty-two being made during the year.

PUBLICATIONS OF THE WORLD HEALTH ORGANIZATION

THE World Health Organization, in accordance with its Charter, publishes a large number of authoritative books and pamphlets in various fields of public health, and in more specialized fields of medicine. The following recent publications will be of interest to a wide spectrum of workers in these fields.

The Animal Health Yearbook for 1964 is the eighth issue of the series of yearbooks bearing this title published jointly by the Food and Agriculture Organization of the United Nations, the World Health Organization and the Office Internationale des Épizooties (FAO–WHO–OIE. *Animal Health Yearbook, 1964*. Pp. vi+316. Rome: Food and Agriculture Organization of the United Nations; London: H.M.S.O., 1965. 17*s*. 6*d*.; 3.50 dollars). The present volume, like its predecessors, contains 316 large pages of detailed information about the incidence and distribution of diseases of livestock all over the world. Printed in English, French and Spanish, it also gives the Latin names of the causative agents of all the diseases listed. A triumph of clear printing and classification of the astonishing range of information collected from replies to questionnnaires sent to the veterinary services in all the countries represented, it constitutes an invaluable summary of the state of animal health all over the world. This year it includes information about the diseases of fish and bees and also an article on the livestock disease position in 1964, and this issue contains for the first time a Russian glossary compiled at the headquarters of the Food and Agriculture Organization from the veterinary literature consulted. An additional valuable feature is the reference index at the end of the volume containing all the terms applied to the various diseases listed in the tables, together with secondary titles, synonyms and causal agents in English, French and Spanish and also other accepted international nomenclatures.

Another valuable publication of the Food and Agriculture Organization is the paperback volume entitled *Fascioliasis and the Liver Fluke* (Food and Agriculture Organization of the United Nations. FAO Agricultural Studies No. 64. Pp. xxi+234. Rome: Food and Agriculture Organization of the United Nations; London: H.M.S.O., 1964. 15*s*.; 3 dollars), the publication of which has been made possible by a generous grant from Ciba, Ltd., of Basle, as a contribution to the Freedom from Hunger campaign. Written by Dr. R. L. Taylor, who, until recently, was deputy director of the Central Veterinary Laboratory of the Ministry of Agriculture at Weybridge, Surrey, this volume carries all the authority of an author whose knowledge of the subject is derived from many years of practical investigation of fascioliasis, in collaboration with his colleagues at the Weybridge laboratory. In this book, Taylor emphasizes the ecological aspects of the disease, which he regards as being a derangement of a naturally healthy relationship between grazing animals and the flukes. He presents the methods of control on farms as artificial adjustments which endeavour to re-establish a normal situation rather than to eradicate a harmful parasite. Taylor does not discuss the serious disease that this fluke may cause in man and, no doubt, he would agree that human fascioliasis is anything but a normal healthy relationship between parasite and host.

Discussing the grave losses caused among livestock by *Fasciola hepatica*, Taylor points out the great difficulty of assessing these accurately, but there is little doubt that, when severe outbreaks of fascioliasis occur, in any country, millions of sheep may be killed by it. He then describes

the anatomy of *F. hepatica*, and its biology, and in an interesting chapter he traces the development, step by step over the years, of our knowledge of the life-history of this fluke, from the first recorded reference to it by Jean de Brie in the time of Charles V of France. He then discusses in considerable detail the ecology, life-history and habitats of the intermediate host, the snail, *Lymnaea truncatula*, which is the chief intermediate host in Britain, although other species of snail are intermediate hosts in other countries. Succeeding chapters discuss the pathogenicity of *F. hepatica*, the pathology of fascioliasis, the clinical features of the acute and chronic forms of the disease, and its treatment. Next is discussed the rapidly fatal black disease of sheep, caused by *Clostridium oedematiens* infecting the liver when this has been damaged by *F. hepatica*. Another chapter discusses the disease caused by *Fasciola gigantica*, the differentiation of this species from *F. hepatica* and the various species of *Lymnaea* that are its intermediate hosts, together with their biology, the losses caused by this species in Pakistan and Uganda and methods used for control of the disease.

In a final chapter, Taylor discusses prospects for the future control of this very grave disease. A valuable bibliography concludes a volume which cannot fail to be of great value and interest to all agriculturists, especially those who are concerned with the rearing of sheep and cattle. Many readers will, no doubt, wish that it could have been issued in a more durable binding.

Aspects of Family Mental Health in Europe (World Health Organization. Public Health Papers, No. 28. Contributed by D. Buckle *et al.* Pp. 123. Geneva: World Health Organization; London: H.M.S.O., 1965. 5 Sw. francs; 8*s.* 6*d.*; 1.75 dollars), by ten European authors, has as its theme that mental illness cannot adequately be treated by confining treatment to the individual who is mentally ill, but must be dealt with in the light of the individual's social environment and of disturbances which affect other members of his family. The papers deal with the work of the School for Parents which originated in Paris and that of the Hampstead Child Therapy Clinic and with family psychotherapy as it is practised in Czechoslovakia. They demonstrate the complexity of the subject and of the various approaches being made to it in different parts of Europe.

Mass Campaigns and General Health Services, by C. L. Gonzalez (World Health Organization. Public Health Papers, No. 29. Pp. 87. Geneva: World Health Organization; London: H.M.S.O., 1965. 4 Sw. francs; 6*s.* 8*d.*; 1.25 dollars), gives the preliminary results of an investigation of this complex subject. It is so complex that it is impossible to summarize briefly the contents of this volume, but it should interest everyone who has responsibility for health services in areas in which mass campaigns against particular diseases may have to be integrated into general health services.

Nutrition and Infection—Report of a WHO Expert Committee (World Health Organization. No. 314. Pp. 30. Geneva: World Health Organization; London: H.M.S.O., 1965. 2 Sw. francs; 3*s.* 6*d.*; 0.60 dollar) discusses the effects of malnutrition on morbidity and mortality caused by infectious disease and experimental investigations of this. Other sections of the report discuss the effect of infection on nutritional investigations, mechanisms of synergism and antagonism and the education of physicians and public health workers. Other sections offer recommendations and suggestions for research.

Special Courses for National Staff with Higher Administrative Responsibilities in the Health Services (World Health Organization. No. 311. Pp. 31. Geneva: World Health Organization; London: H.M.S.O., 1965. 2 Sw. francs; 3*s.* 6*d.*; 0 60 dollar) gives the views of a World Health Organization Study Group on the training required by those who adopt health services as a career. Annexes give details of existing training programmes in the University of Zagreb, the School of Hygiene in the University of Toronto, the Johns Hopkins University, the National Institute of Health Administration and Education, New Delhi, and in the Staff Training Programme of WHO.

Diabetes mellitus—Report of a WHO Expert Committee (World Health Organization. No. 310. Pp. 44. Geneva: World Health Organization; London: H.M.S.O., 1965. 3 Sw. francs; 5*s.*; 1 dollar) discusses the natural history, detection, prevention and control of diabetes and the employment of diabetics, with suggestions for research on the disease.

Vol. 19, No. 11, of *WHO Chronicle* (price 1*s.* 2*d.* from H.M.S.O., P.O. Box 569, London, S.E.1) discusses hospital organization in developing countries, the health problems of adolescence, the World Health Organization's programme on nutrition and international non-proprietary names given to pharmaceutical preparations. In the "Notes and News" section there are notes on cholera outbreaks in Iran, Afghanistan and the U.S.S.R., on mycoses in Africa and on the collaboration between the World Health Organization and the London Zoo in comparative medicine.

Dependence-producing Drugs (World Health Organization. No. 312: WHO Expert Committee on Dependence-producing Drugs—Fourteenth Report. Pp. 16. Geneva: World Health Organization; London: H.M.S.O., 1965. 2 Sw. francs; 3*s.* 6*d.*; 0.60 dollar) contains an annexe which gives a list of drugs that are under international narcotics control.

The August issue of the *WHO Chronicle* (price 1*s.* 9*d.*, from H.M.S.O., P.O. Box 569, London, S.E.1) contains a report on the Proceedings of the eighteenth World Health Assembly held in Geneva in May 1965, an article on the work of the World Health Organization in relation to population problems, and another on activities assisted by the World Health Organization in the campaign against tuberculosis, an account of the report of the World Health Organization Expert Committee on nutrition in pregnancy and lactation, together with the customary feature entitled "Notes and News" and short reviews of three World Health Organization publications. The September issue of this *Chronicle* contains articles on malaria eradication in 1964, research on cardio-vascular diseases, work on tuberculosis assisted by the World Health Organization, the chemoprophylaxis of primary tuberculosis, and a useful article on changes in health legislation in various countries in Europe, South America, India and Australia.

World Health Organization Technical Report Series No. 309 is a joint publication with the Food and Agriculture Organization entitled *Specifications for the Identity and Purity of Food Additives and their Toxicological Evaluation, Food Colours and some Antimicrobials and Antitoxidants* (World Health Organization. Eighth Report of the Joint FAO/WHO Expert Committee on Food Additives. Pp. 25. Geneva: World Health Organization; London: H.M.S.O., 1965. 2 Sw. francs; 3*s.* 6*d.*; 0.60 dollar). It emphasizes the need for international establishment of specifications for the identity and purity of food-additives, which should not only protect the consumer, but should also help the manufacturers and those who process foods.

No. 26 of the invaluable series of World Health Organization Public Health Papers, written by Prof. E. M. Blackett, of the University of Aberdeen, deals with the grave subject of domestic accidents, which, unlike the road accidents which are so often in the news, receive little publicity (World Health Organization. *Domestic Accidents*. Pp. 137. Geneva: World Health Organization; London: H.M.S.O., 1965. 6 Sw. francs; 10*s.*; 2 dollars). Yet in many countries deaths due to domestic accidents are comparable in number to those due to tuberculosis. The study of them on an international basis is complex and much of the literature about them is obscure, yet these accidents are, this publication suggests, likely to

become more and more a public health problem in the future. Control of disease and the resulting increase of the population are leading to increasing numbers of old people and children, who are particularly liable to domestic accidents. Mechanization in the home also tends to increase their number and variety.

No. 27 of the same series is entitled *Trends in the Study of Morbidity and Mortality*, and it contains articles on this subject by fourteen contributors (World Health Organization. Public Health Papers, No. 27: *Trends in the Study of Morbidity and Mortality*. Dario Curiel and thirteen other authors. Pp. 196. Geneva: World Health Organization; London: H.M.S.O., 1965. 8 Sw. francs; 13*s*. 4*d*.; 2.27 dollars). In general, the articles survey the methods now in use for obtaining statistics on morbidity and mortality in the United Kingdom, Europe, Romania, Japan and India, and the problems of making the data obtained internationally comparable. There is need for further research into methods of reporting and for the establishment of some degree of uniformity.

RESEARCH FACILITIES AVAILABLE TO INDUSTRY AND THEIR INTER-RELATION

CLOSER collaboration between industrial, governmental, academic and independent research establishments was the principal theme and objective of the symposium arranged jointly on September 14, 1965, by the Scottish Office of the Ministry of Technology and the Arthur D. Little Research Institute, at the Royal Society of Edinburgh. The seven speakers at the symposium were followed by Sir Harry Melville, who described the varied work of the newly formed Science Research Council, of which he is chairman, this lecture being the first of the Arthur D. Little 1965–66 series of Acorn Lectures on various scientific topics.

Mr. P. M. Thomas (managing director, William Beardmore and Co., Ltd.), in the chair for the morning session, directed attention to the necessity for industry to make proper use of research facilities and so be aware of the present status of any topic relevant to the particular industry and the appropriate place to which to direct problems.

Prof. Manfred Gordon (Department of Physical Chemistry, University of Strathclyde) said that his University, formerly the Royal College of Science and Technology, always had a technical bias and strong links with industry. For example, the idea of industrial liaison officers, whose purpose is to establish co-operation between an academic establishment and industry, originated in 1956 at the then Royal College of Science and Technology. The University and the National Engineering Laboratory have special relationships and that some of the National Engineering Laboratory staff are registered as Ph.D. students. Many of the University staff act as consultants, but Prof. Gordon expressed the desirability of younger members spending a few weeks of the summer vacation in industry. Strathclyde now uses closed-circuit television for teaching, which could be a valuable technique to assist firms with their training problems. The computer service at the University was also mentioned.

Dr. Magnus Pyke (manager, Glenochil Research Station, Distillers Co., Ltd.) recalled that a few years ago some firms believed in leaving the research staff alone, in the hope that profitable ideas and processes would emerge. This procedure was found very expensive and not very profitable. To-day, practical problems are chosen for the research staff. However, Dr. Pyke stressed that applied research should be tackled at an intellectual depth in order for the results to be financially worth-while and stimulating to the staff. Non-secret technical know-how should be more widely disseminated between firms by personal contacts and a new journal.

The problem of assimilating the scientific literature could, he suggested, be solved by using computers to store information which would be released by 'telephoning'. Dr. Pyke, like other speakers, deplored the gap between industry and academic establishments in Britain, a situation which does not occur to the same extent on the Continent or in the United States, and called for more industry-orientated projects for research students in order to counteract an 'ivory tower' attitude.

Mr. F. D. Penny (deputy director, National Engineering Laboratory) gave a short historical survey of Government laboratories. Initially, during the seventeenth and eighteenth centuries, these were for defence purposes; later, civil laboratories were established, the Geological Survey being founded in 1835 and the Inland Revenue Laboratory in 1842. Others, of which the National Physical Laboratory was the first in 1900, were intended to determine fundamental and applied standards. In 1915 the important White Paper setting up the Department of Scientific and Industrial Research, which represented a conscious effort by the Government, appeared to take responsibility for improving industrial progress. Research programmes were not evolved in isolation but were controlled by committees of leading academics and industrialists.

The National Engineering Laboratory was opened in 1947, and, as with other Government laboratories, the work can be classified as follows: (1) particular problems —testing and longer-term research (the latter represents 10 per cent of the total work at the National Engineering Laboratory); (2) safety, for example, tests on gas cylinders; (3) problems applicable to a class of industry but not sponsored by any firm, for example, investigations of metal fatigue; (4) special facilities—testing of pumps and turbines; (5) research in a field of industrial importance in which the Government believes there should be a greater rate of innovation; (6) standards of goods for export; (7) advisory services.

The National Engineering Laboratory issues reports (8,000 total so far) and papers in scientific journals, welcomes visitors and holds open days. The total staff is 800, and they spend about half their time on research and half on application.

Dr. H. P. Stout (director of research, British Jute Trade Research Association) pointed out how a research association benefits especially the smaller firms of an industry, since such firms usually cannot afford adequate scientific staff and, where facilities are available, may have difficulty in the recruitment of staff because there is no suitable environment for them. The research association can provide a scientific atmosphere, but there is still the problem of getting *en rapport* with the firms. Commenting on the statement sometimes heard that arts graduates were more use as management material than science graduates, he thought this was usually the result of the scientist being given a specialist function and not acquiring the broad training and experience which was given to the arts man. Dr. Stout noted that innovation costs money and manufacturers are unwilling to develop ideas where the market is small, even after the research association has done the 'spade work'. He instanced new weaving machinery developed

for the woollen and cotton industry which had not been adapted for the jute industry because of its comparatively small size.

Opening the afternoon session, the chairman, Dr. E. A. C. Chamberlain (divisional chief scientist, National Coal Board), questioned whether Britain was really research-oriented and said that Britain tends to ignore the real achievements which have been made. Personal contact is essential to break down the barriers of ignorance, laziness and snobbery between scientists, technologists and industrialists, and he therefore welcomed this symposium.

Dr. F. N. Woodward (director, Arthur D. Little Research Institute) recalled the Jubilee Memorial Lecture given to the Society of Chemical Industry by Prof. J. W. Mitchell, in which he depicted the four sources of scientific information, that is, industry, academic institutions, Government laboratories and sponsored research institutes, as standing at the corners of a tetrahedron. In the United States, industry uses the four sources equally and there is free movement of people and ideas between them—to which is ascribed the fact that industry in the United States has a growth-rate twice that in Britain. He went on to describe the growth of sponsored research institutes, particularly those of Arthur D. Little, first in the United States and later in Europe. Enumerating the reasons for the rapid growth of sponsored research institutes, Dr. Woodward cited their independence; the fact that they are professional business organizations without other ties such as teaching; and their versatility, speed of action and flexibility through a multi-disciplinary staff (which includes management skills). The sponsored research institute obviates the need for a firm to augment its own research facilities to deal with special problems. They have close ties with academic establishments and use academic consultants regularly. While working for a firm they make a point of trying to become a temporary but integral part of the management.

Prof. W. E. J. Farvis (Department of Electrical Engineering, University of Edinburgh), while speaking of the relationships between industry and university engineering departments, complained about the difficulty of deciding on suitable student curricula in view of the changing face of the engineering industry. He supported the concept of colleges of advanced technology and the Diploma in Technology, and deplored the present desire, partly based on snobbery, for such colleges to become universities. Prof. Farvis wished to see a better liaison and understanding between industry and academies. Thus, industry could help engineering departments and themselves by promoting research projects and releasing staff to help teach design. Next year, in the Department of Electrical Engineering at Edinburgh, design experiments will be included in the curriculum to help the student to feel that he is part of industry as well as of a university. Prof. Farvis would like suggestions from firms as to small problems, possibly of dubious solutions. Little would be lost financially if there were no satisfactory outcome, but meanwhile students were being trained while worrying at a practical problem in close contact with industry.

W. S. Robertson (chief executive, Scottish Council for Development and Industry) spoke fluently about the past, present and future industrial situations in Scotland. Industrial development in Scotland first 'sheared off' from the rest of the world during 1880–90 although the effects were scarcely noticeable until the 1920's. Until 25 years ago, industry in Scotland suffered from two weaknesses: (1) there was no production of engineering components in quantity; (2) there was little applied research. Scotland had only a weak technological push, there were many gaps in the industrial scene, and few opportunities for graduates. Since 1925 much progresss has been made in getting quantity production and fairly good progress in applied research. Mr. Robertson said that distribution as well as number should be considered with regard to graduates. He defined:

Expansive force = No. of scientists and engineers multiplied by communications

The pattern of industry is closely associated with the distribution of Government defence spending. Thus, in south-east England there are many Government research laboratories; once these had been established, industry rose up to feed them. The benefits from the National Engineering Laboratory, founded in 1947 at East Kilbride, have begun to mature and Mr. Robertson predicted that this area of Scotland will become one of the best engineering centres in Europe. Such experience suggests the need for similar Government spending to stimulate industry in other parts of Scotland and the United Kingdom. For a thriving research community, communications, both physical and intellectual, are vital, and he instanced the growth of the electronics industry in the area around Edinburgh, well served by air and rail, which is expanding at a higher rate than anywhere else in Britain. The air service north of the industrial belt, however, is poor, and no direct communication exists between Scotland and the European Continent.

Sir Harry Melville (chairman, Science Research Council), speaking on "Collaboration between Industry and Government in Fostering Scientific Research", began by asking for better communications and exchange of personnel between centres of learning, industry and Government laboratories. The Science Research Council, inaugurated in April 1965 following the replacement of the Department of Scientific and Industrial Research, has promoted, or will promote, research studentships, fellowships and industrial fellowships at academic institutions, and make grants towards research work undertaken in a research association, sponsored research institute or industrial laboratory, provided the work is of outstanding public and scientific interest and the recipient of the grant uniquely qualified to undertake it.

The Science Research Council is paying about £4 million a year in grants to universities for expensive equipment. Usually the Council stipulates that the equipment be shared with other departments and available to outside users. An outstanding example is the Scottish Universities Reactor, which cost £500,000. However, some equipment, such as particle accelerators, costing up to £10 million, is of little direct use to industry.

In the United States the same proportion of the national income is spent on research as in Britain but the total is ten times as great. Hence, while in the United States some of the national income can reasonably be spent on pure research from which no practical results are expected, Britain should not, he believes, do so as a rule. The Science Research Council, however, does make exceptions, one of which is support for a very expensive space science programme.

During discussions several deprecated the 'gap' between the industrial and academic spheres. It was generally agreed to be mutually advantageous for institutions of higher learning to undertake problems suggested and partly supported by industry and Government departments; however, Prof. Farvis quoted Sir Edward Appleton's remark that research, even if apparently trivial, serves to train the student into thinking in an original manner—which is what is required of the graduate in industry. There is need to attract creative minds into industry. The need for personal communication was emphasized: research workers should go out to non-scientists to persuade them of the desirability and application of particular research ideas.

We look forward to translation of the sentiments of the symposium into action.

FUNDAMENTAL CANCER RESEARCH

THE nineteenth annual symposium on "Fundamental Cancer Research", sponsored by the M.D. Anderson Hospital and Tumour Institute of the University of Texas, was held at Houston, Texas, during March 4–6, 1965, the subject being "Development and Metabolic Control Mechanisms and Neoplasia". The sessions at the Symposium dealt with the following topics: "Biosynthesis and Control Mechanisms", "Molecular Basis of Early Development", "Molecular Basis of Later Development and Control" and "Comparative Studies of Control Mechanisms in Normal and Neoplastic Tissues". Several papers dealt with various aspects of the currently accepted sequence of events in biosynthesis, namely, DNA → RNA → protein, and especially aspects relating to development and differentiation.

R. M. S. Smellie (Glasgow) gave a review of the enzymatic synthesis of nucleic acids in bacteria and animal tissues, describing the various RNA and DNA polymerases involved. He pointed out that DNA is present in animal cells as a complex with protein, and that the mechanism by which it directs synthesis of new DNA remains to be determined. One function now generally assigned to histones is that of acting as gene repressors and they would accordingly play an important part in differentiation and development. Since different RNA fractions of the cell differ in their base composition, it is possible that the action of RNA polymerase is restricted to transcribing certain DNA regions in the nucleus. One approach to the study of these problems is by investigations on the synthesis of RNA in isolated nuclei and nucleoli the structural organization of which is maintained as intact as possible. R. B. Hurlbert (Houston), working with such systems, has presented evidence that the base composition of the newly formed labelled RNA can be altered by pretreatment of nuclei with different fractions of histone, or with trypsin to remove part of the histone originally present. The synthesis of the labelled RNA is inhibited by actinomycin *D*, indicating that the RNA is formed on a DNA template.

In the past few years a new approach has been developed in the study of the functions of hormones involved in development and growth. It is thought that their action is mediated through cellular mechanisms regulating nucleic acid and protein synthesis in their target tissues. It is possible that, in response to hormones, particular types of *m*RNA are formed; these then direct the coding of particular proteins, including enzymes which bring about specific developmental changes. This was discussed by J. R. Tata (London), who has shown that RNA polymerase of liver nuclei is increased by administration of thyroid and growth hormones. The effect is additive, indicating that each hormone enhances the formation of different fractions of RNA, including *r*RNA and *m*RNA. Also, incorporation of amino-acids into protein by mitochondria and microsomes is stimulated by thyroid hormone. Another example of the effect of thyroid hormone which was mentioned is the induced metamorphosis in the frog. The effects of other hormones involved in development were also discussed. In insect metamorphosis, the hormone ecdysone controls new differentiation processes by regulating the activity of specific genes involved in these processes (U. Clever, Lafayette, Ind.). A similar conclusion is arrived at also from the work of J. D. Wilson (Dallas, Texas) on the binding of [^{3}H]testosterone to chromatin fragments of nuclei from duck preen glands; the hormone binds to the fragments which are the major sites of synthesis of RNA in the nucleus. S. Cohen (Nashville, Tennessee) presented work on the isolation from mouse salivary gland of a protein of low molecular weight which stimulates epidermal growth. The stimulation of RNA and DNA synthesis in organ culture by this factor was also demonstrable.

Comparison of *m*RNA templates in rat liver and hepatomata were discussed by H. C. Pitot (Madison, Wisconsin). Differences in the lifetime of templates for synthesis of enzymes concerned in amino-acid degradation were stated to occur in liver and hepatomata. H. G. Wittmann (Tübingen) reported work that is being carried out on the correlation between nucleotide changes in an *m*RNA and the resulting amino-acid replacements in the protein synthesized. This is done in tobacco mosaic virus RNA and its coat protein. An investigation of mutants of the virus obtained by treatment with mutagens has been carried out.

Investigations of the RNA and ribosome content of the unfertilized amphibian egg and embryo by D. D. Brown (Baltimore, Maryland) have shown that, while ribosomes are present mainly as monosomes in the unfertilized egg, polysomes are predominant in the early stages of the developing embryo, indicating that either more *m*RNA is formed or that its attachment to ribosomes is then initiated. Also the *s*RNA content of the egg is extremely small —possibly a further factor controlling protein synthesis. Modification of *s*RNA, which acts as an adaptor in protein synthesis on polysomes, may occur prior to differentiation, as shown by the work of N. Sueoka (Princeton, N.J.), who found that, as a result of infection of *Escherichia coli* with phage, a modified type of leucyl-*s*RNA is formed. S. Penman (New York) reported work on the relationship between protein synthesis and lipid metabolism in HeLa cells infected with polio virus. The polysomes of infected cells are found attached to lipoprotein membranes in contrast to those of normal cells. The infection is also accompanied by a stimulation of the lipid metabolism of the cell.

In a cell-free system *in vitro*, protein synthesis can be investigated by the rate of incorporation of labelled amino-acids; the presence of the necessary factors can thus be verified. The attachment of ribosomes to *m*RNA to form polysomes and the binding of aminoacyl-*s*RNA are prerequisites for polypeptide synthesis. The role of several factors involved in these processes, including enzymatic ones, has been discussed by R. S. Schweet (Lexington, Kentucky) and by H. Noll (Evanston, Illinois). The interchangeability of the various fractions from Novikoff tumour, rat liver and *E. coli* in such *in vitro* systems has been studied by A. C. Griffin (Houston). The components of the systems included amino-acid-activating synthetases, ribosomes, transfer enzyme fractions, *s*RNA and [^{14}C]aminoacyl-*s*RNA. It is interesting that, in general, a much greater interchangeability was observed between the components of tumour and liver than between those of *E. coli* and the mammalian tissues.

Aspects of metabolic regulations at the enzymatic and metabolic levels were discussed at the Symposium. Since the discovery, by Monod and his co-workers, of allosteric effects, many enzymes which show these properties have been described. Some enzymes exist in two configurations while others occur in sub-units which show reversible association and dissociation. A discussion of the characteristics, kinetics and behaviour of such enzymes towards substrates and inhibitors as compared with those of the more general type of enzyme was given

by C. Frieden (St. Louis, Missouri). Regulation of substrate concentration in the cell is another factor in control of biochemical reactions. Injection of creatine into chick embryo inhibits the endogenous formation of creatine by repressing the first enzyme involved in its biosynthesis. This inhibition is specific to creatine since its structural analogues are not effective (J. B. Walker, Houston). A similar negative feed-back control is found in the case of cholesterol synthesis by normal and regenerating liver. However, it is interesting that such a feed-back system is absent in all spontaneous and induced hepatomas tested (M. D. Siperstein, Dallas). Changes in the levels of substrates used as building-blocks in the synthesis of polysaccharides and in the activities of the enzymes concerned, and their correlation with different stages of differentiation of the slime mould, were discussed by B. E. Wright (Boston, Massachusetts). In another contribution, W. J. Rutter (Urbana, Illinois) discussed the two variants of fructose-diphosphate aldolase that have been found in animal tissues. During the development of the embryo there is a change-over from the predominance of one to that of the other. Two different metabolic roles are suggested for the two enzymes. Since the enzymes have distinct differences immunologically and in their fingerprint patterns, it is possible that they are coded by separate regions on the genome at different stages of cellular differentiation.

The Bertner Foundation Award for Outstanding Achievement in the Field of Cancer Research was presented to Prof. E. Chargaff (New York), who gave the Bertner Foundation Lecture at the Symposium on the topic: "On the Biological Consequences of Base-Pairing in Nucleic Acids". He discussed problems relating to the study of the primary structure of DNA. Although the regularities in the base composition of DNA apply to the whole DNA molecule, it is not known how far this is true of any given segment of the molecule. Several chemical methods for partial degradation of DNA have been developed. Clusters of nucleotides from the DNA chain can thus be obtained and identified and this may constitute a valuable approach to base sequence studies.

* Generous travel grants from the Wellcome Trust and the British Empire Cancer Campaign enabled me to attend this Symposium.

POSSIBLE STRUCTURES FOR TRANSFER RIBONUCLEIC ACID: A TRIPLE-STRANDED MODEL

By Dr. WILHELM GUSCHLBAUER*
Institut de Biologie Physico-chimique, 13 Rue Pierre Curie, Paris 5

ALTHOUGH considerable interest has been shown in the ribonucleic acid species called soluble, acceptor or transfer RNA (*t*RNA)[1] ever since its discovery[2,3], few concrete suggestions have appeared as to its structure. It is now believed from hydrodynamic measurements, X-ray investigations and electron micrographs[4] that *t*RNA is a rather rigid rod, although the evidence is not too convincing since these techniques are presently not refined enough to settle this point. Fresco *et al.*[5] first summarized the experimental evidence existing and brought forward two structures which are the essential basis of all models suggested to date. A chain bent back on itself in the form of a hairpin to form a helix, and a model with two hairpins joined together (V-model) were proposed. These authors believed that the helices in either model were interrupted to a varying degree by loops. A single completely helical (DNA-like) hairpin was also proposed[6-8]. Brown *et al.*[9] also envisaged the possibility that the hairpin and V model could be interchangeable. Sequence studies on unfractionated *t*RNA[10] led to a model only about 70 per cent helical where the bend was expanded to a large loop of about 15–20 nucleotides accommodating the anticodon and the rare bases. Since by definition *t*RNA has two distinct properties, that is accepting and transferring amino-acids, and since the phosphate backbone will provide little specificity for recognition, two non-helical regions should be necessary which might or might not be separated by helical regions. Novelli and others[11] suggested distinct acceptor and transfer sites, and recent work by Weill *et al.*[12] further supports the concept of two different operational sites, difficult to reconcile with the hairpin model, although evidence to the contrary has been presented too[13,14]. Spectral studies by Felsenfeld and Cantoni[15] point to a clustering of *A–U* and *G–C* pairs in serine specific *t*RNA, similar to previous findings of Fresco[16], who first reported two-step melting profiles for amino-acid specific *t*RNAs. From difference spectra studies on these purified *t*RNAs it was inferred[17] that each molecule contained two helical regions which melted separately and co-operatively. These data suggested that the ratio of *A–U* to *G–C* pairs was always considerably lower in the higher melting region.

All these reports have centred on a highly helical double-stranded structure of the Watson–Crick type, although no rigorous evidence has been presented so far for or against double strandedness in *t*RNA. In this article a triple-stranded model for *t*RNA will be offered to emphasize that other than double-stranded structures cannot be ruled out *a priori* at present. Evidence will be brought forward which will demonstrate the feasibility, advantages and disadvantages of such a structure as compared with various double helical models.

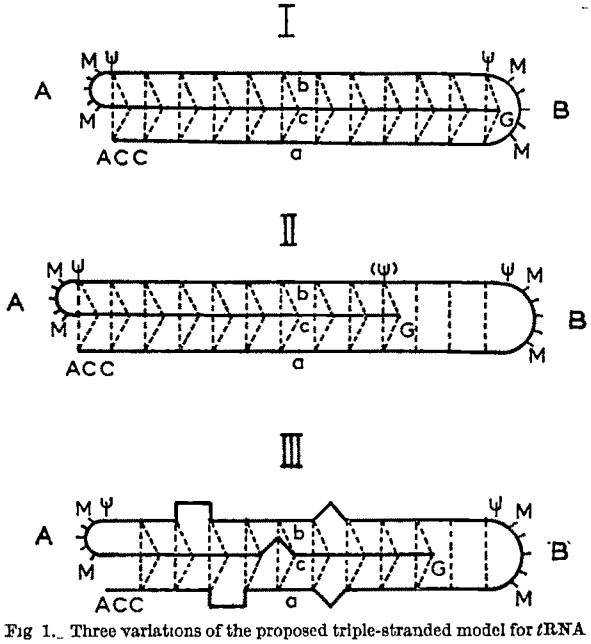

Fig 1. Three variations of the proposed triple-stranded model for *t*RNA

* Fellow of the Helen Hay Whitney Foundation, New York. Present address: Département de Biologie, Centre d'Etudes Nucléaires de Saclay, B.P. 2, 91 Gif-sur-Yvette, France.

The possibilities for a triple-stranded model for *t*RNA are shown schematically in Fig. 1. Model I involves three equally long strands, hydrogen bonded to each other and connected with each other by two loops of at least three but probably not more than five or six nucleotides. The *Gp* end of the molecule could be hydrogen bonded too, as well as the *pCpCpA* amino-acid acceptor terminal. Neither, however, needs to be bonded. This would place the amino-acid acceptor end in close vicinity of the loop *A*, which could serve as the attachment and recognition site for the amino-acid RNA synthetase.

The second loop *B* would contain the anticodon (either a triplet[18,19] or a doublet[20]) to attach to the messenger RNA. In the present model the methylated purines are placed on the first and last position of each loop (*M*, Fig. 1), where they could serve as punctuation bases because of their incapacity to form hydrogen bonds[21]. Pseudouridine residues, because of their strong hydrogen-bonding capacities[22], are pictured to be on the ends of the strands in the helix (ψ, Fig. 1), acting like clamps and holding together the rather short helices of 20–30 triples. ψ–*U* and the methylated purines would thus be immediate neighbours in the sequence. It is interesting to note that several investigators[23] have found oligonucleotides containing one ψ–*U* residue and one methylated purine. In either model the rare bases would occur in the centre third of the molecule in agreement with the results of Nihei and Cantoni[24]. The completely triple-stranded model I should be considered as a special case of the more general model II.

In model II one strand is shorter than the two others, so that only part of the helix is triple stranded, while the rest is double stranded. The two loops as well as other features are essentially similar to model I. Another ψ–*U* residue might be pictured on strand *B* close to the area where the *Gp* terminal could be bonded. It is clear that looping out in either one of the three strands could be envisaged to accommodate non-fitting bases[25], as depicted on model III.

Either of these models could serve as the 'adaptor'[2], combining the properties suggested for the double-stranded models for the attachment to the messenger RNA with the additional feature that the acceptor site of the model will also be specified to accommodate the enzyme for the attachment of the amino-acid to the *t*RNA. This would also be the cause with the double-stranded V-shaped model. However, the latter would not be a single rigid rod, since its centre loop will permit free rotation of the two arms. The second loop would also be rather far away from the amino-acid accepting end, except if the centre loop would serve as the attachment or coding site[6]. One of the main advantages of the present model is its compactness, which would render it less susceptible to attack and degradation.

Several years ago Stent[26] and Zubay[27] had already shown in their investigation of the possible arrangement of messenger RNA during its synthesis on DNA that triple-stranded nucleic acid helices are feasible on spatial grounds. The fact that a single strand of RNA can be accommodated in the large groove of the Watson–Crick helix with ample possibility for hydrogen bonding to the already existing base pairs without distortion of their arrangement to form triples seems unlikely to be fortuitous in Nature. Such a scheme can essentially be applied to the present triple-stranded model (substituting *U* for *T*). Zubay[27] suggested two models, each involving four different triples. Each triple consists of a Watson–Crick base pair plus an additional base in the 'third strand'. They are summarized in Table 1.

Table 1. BASE TRIPLES
(After Zubay (ref. 27))

Model *A*		Model *B*	
Watson–Crick pair	Third strand	Watson–Crick pair	Third strand
U+A	*C*	*U+A*	*A*
A+U	*G*	*A+U*	*U*
C+G	*U*	*C+G*	*G*
G+C	*A*	*G+C*	*C*

Although there is experimental evidence from polynucleotide studies for only two of the complexes of model *B*[28,29] so far, model *A* cannot be excluded *a priori*.

After melting of the third strand a double helix of about 20 base pairs will remain[30]. Either strand *A* or strand *C* in Fig. 1 could be topologically the third strand. *A priori*, there seems to be no reason to assume that, if, for example, the acceptor strand *A* were the third strand in one amino-acid specific *t*RNA, it should not be so in all types of *t*RNA. The experiments of Monier and Grunberg-Manago[31] point indeed to a structural differentiation among different *t*RNAs.

The difference spectra studies of Fresco *et al.*[17] make model I less probable. Three results of this work must be taken into account: (*a*) the co-operativeness of the melting of each region (which seems to be unequivocally proven by these experiments); (*b*) the length of each region is not equal; (*c*) there are less *A–U* containing complexes (pairs or triples) in the higher melting region. This latter region seems to be always shorter in the three types of *t*RNA studied (between 30 and 45 of the total helix) than the lower melting one. This, however, need not necessarily be true for all other *t*RNAs. The absolute molar extinctions of the difference spectra of the various transitions of the *G–C* series are at present not sufficiently exactly known to allow any definite conclusions so far as strandedness is concerned. In addition the shapes of the difference spectra between the transitions 2 to 1 and 3 to 2 strands are quite similar[28,29], which could reconcile these results even with model I. In addition, the additivity of component difference spectra which seem well documented for long chains of DNA[17] and RNA[32] might not necessarily hold exactly for short RNA helices. Model II would be in agreement with these findings.

There might also be another, at first sight less attractive, possibility for the melting of the third strand which will not always lead to a Watson–Crick type double helix. Donohue[33] showed that 29 different base pairs are possible, several of which could appear in a helix with Watson–Crick dimensions. Some distortions of the bases would, however, be necessary to form a double helix after removal of the third strand. Such unconventional base pairs would probably be present only in small amounts. The difference spectra studies of Fresco[16,17] exclude extensive bindings of this kind. Fresco and Alberts[25] also showed that looping out would be the preferential arrangement for non-complementary bases. Recent work by Bautz and Bautz[34], however, suggests that non-complementary bases could as well be accommodated simply by stacking in the helix, without hydrogen bonding. Model-building studies[35] make several other triples quite possible which do not have a Watson–Crick base pair as basis, and might even involve other bases like I. It is clearly not to be expected that difference spectra studies will distinguish single pair or triple arrangements of this type.

All macromolecular and biological features of *t*RNA known so far can equally well be applied to the suggested triple-stranded model as to the double-stranded forms. There are, however, several findings which would be difficult to reconcile with a double-stranded model, but would be expected in a triple helical structure.

(1) The reluctance of polyribonucleotides to form double-stranded structures makes heavy demands on a double helical model of *t*RNA. It has been shown that mixtures of poly *A* and poly *U* can form both double- and triple-stranded helices, depending on the conditions[16,28]. In the *G–C* series only recently attempts to form a double-stranded structure were successful[29]. A triple-stranded complex poly (*G+C+C*) will be formed exclusively, however, if short chains are involved in the helix formation. Helices of poly *X* with poly *A* or poly *U* are only triple-stranded, as well as all complexes involving 5-substituted poly *U* with poly *A*[36]. Poly ψ*U* seems

to form an unusually strong triple helix with poly *A* [22] and probably also with other homopolymers. Recently, however, the RNA of Rheo virus has been found to be double-stranded and several reports on double-stranded RNA have appeared since[37–39].

(2) Two-step heating curves[16] would be expected for the triple-stranded models of *t*RNA. The implications of the difference spectra studies[17] have been discussed here.

(3) Holley *et al.*[40] and Cantoni *et al.*[41] have shown that the base composition and sequence of purified amino-acid specific *t*RNAs does not always reflect a complete Watson–Crick scheme. The recently published complete sequence of alanyl-*t*RNA shows clearly that only a loop-containing model[40] could reconcile the sequence with a Watson–Crick double helix. It can be accounted for in terms of a triple-stranded structure with a minimum of non-helical bases[35].

(4) Marciello and Zubay[42] examined the reaction of formaldehyde with the amino groups of *A*, *G* and *C* of *t*RNA which do not react, if they are bonded in a helix, as a function of temperature. Additional attacking sites were freed at lower temperatures because of the denaturing effect of formaldehyde. The extent of the reaction increased stepwise and it was concluded that there are three groups of bases according to their reactivity. The authors estimated that the last group (the least reactive and strongest bound bases) comprised about two-thirds of the total bases or about 24 base pairs, which is in excellent agreement with the number of base pairs and the relation to the total molecule for the second double-stranded region in the present model[30]. A V-shaped model with one longer, *G–C* rich branch would also account for this result.

(5) The fact that only recently have satisfactory X-ray diffraction patterns[7] of what supposedly was *t*RNA [38] been obtained, and this only after special pre-treatment[8] which involved chain breakage, clearly shows that *t*RNA can be obtained in a DNA-like structure only under very special conditions, if at all, while several other, double-stranded RNAs [37] have given very satisfactory X-ray pictures. Unfortunately the only existing X-ray data on triple-stranded polynucleotides (poly I) are rather inconclusive[43]. It is clearly evident, however, that all other physico-chemical techniques, except very refined X-ray work, will not solve the problem.

(6) Monier and Grunberg-Manago[31] showed that polynucleotide phosphorylase (PNPase) attacked unfractionated *t*RNA to only about 30 per cent at 37 degrees. The acceptor activity for several amino-acids was unchanged, indicating that these *t*RNAs were not attacked at all. This finding is apparently incompatible with a non-hydrogen-bonded *pCpCpA* amino-acid acceptor end, since PNPase should remove these three nucleotides first on all molecules, if they are not hydrogen bonded. Only the V-shaped model[5,8] could account for this finding among the double-stranded models. In a triple-stranded model attack by PNPase will be possible only if the *pCpCpA* carrying branch *A* is the third (lower melting) strand. If strand *C* (with the *Gp* terminal) will melt lower, no attack by PNPase would be possible, since this enzyme does not act on the 5′-phosphate end of the polynucleotide chain. Such *t*RNAs should be resistant to the action of this enzyme up to about 60°, where in the cases tested so far[16] the second helical region will start to melt, thus freeing the acceptor terminal too, which now can be attacked by the enzyme. When phosphorolysis is carried out at 60°, complete digestion is indeed obtained[44].

From the foregoing it is clear that a triple-stranded model for *t*RNA is feasible and cannot be excluded *a priori*. It should, however, be pointed out that, although less attractive, even a double-helical structure could form a triple-stranded arrangement under suitable conditions, and vice versa, if both schemes of Zubay[27] (and possibly the base pairs of Donohue[33]) are considered. Such changes in conformation could possibly happen during the transition *in vivo–in vitro*, particularly since the formation of an artefact is known to occur in the case of TMV–RNA, as pointed out by Timasheff *et al.*[45]. A change in conformation of this kind might also distinguish charged from uncharged *t*RNA molecules. Although no differences in molecular weight (determined hydrodynamically) have been found[46], there is some, admittedly sketchy, evidence that *t*RNA might have different shapes under different conditions[47]. Here again, only X-ray techniques can be invoked to settle the question. Therefore, even a complete nucleotide sequence[40] of an amino-acid specific *t*RNA will not clear the problem of *in vivo* secondary structure. In addition to the several double-stranded models proposed by Holley *et al.*[40] (which incidentally do involve some base pairs other than *A–U* and *G–C*), at least two rather satisfactory three-stranded structures can be constructed with a few loops and little complexing other than in the schemes of Zubay[35].

Of several double-stranded models suggested the V-model or some variation of it[5,8] has the most experimental support. Particularly an arrangement where the anticodon triplet is envisaged between the two branches[7] would also account for most of the results in the literature.

Considering the aforementioned results, triple-stranded arrangements could also be involved in other conformational problems of RNAs. Although double-strandedness has now been well documented for Rheo virus[39] and several other RNAs [37], triple-strandedness might be invoked for the structure of the RNA of spherical viruses and of ribosomes where close packing would be favoured by stabilized hydrogen-bonded structures. Another case which might involve triple-stranded hydrogen bonding is the 'three body problem' ribosomes–messenger–*t*RNA. Since, as shown by Zubay[27], for any base pair more than one triple could be possible, the third base could be any one of the four bases (Table 1). This might be a clue to the degeneracy of the genetic code.

I thank Dr. Marianne Grunberg-Manago and Prof. Jacques R. Fresco for their advice. I also thank Drs. R. Baldwin, J. Brahms, M. D. Kamen, V. Luzatti, J. Massoulié, F. Melchers, A. M. Michelson, R. Monier, E. G. Richards, A. S. Spirin, M. N. Thang, H. G. Zachau and B. H. Zimm for their criticism.

[1] The following abbreviations are used: *t*RNA—transfer (soluble) ribonucleic acid; *A*, *G*, *U*, *C*, *T*—the five common bases; I—hypoxanthine; *ψU*—pseudouridine; 5-met-*C*—5-methyl-cytosine, *A–U* and *G–C*—the Watson–Crick base pairs; PNPase—polynucleotide phosphorylase; TMV—tobacco mosaic virus.

[30] Assuming an average molecular weight of 350 per nucleotide residue, model I would give three branches of about 24 nucleotides (mol wt 8,500) each, plus two loops of five nucleotides (mol. wt. 1,800) each, totalling a molecular weight of about 29,000. In Model II two branches with 27 nucleotides (mol wt. 9,500), one branch with 15 nucleotides (mol. wt. 5,000) and two loops with five nucleotides (mol. wt 1,800) each would add up to about 28,000 mol. wt Similar considerations hold for the loop containing model III. It should be pointed out that models II and III could be different in different *t*RNAs, for example, two branches with about 30 residues (mol. wt. 11,500), one strand with about 10 residues and the two loops (mol wt 3,500), totalling about 29,000 mol. wt

GENETICALLY DETERMINED VARIATION OF ADENYLATE KINASE IN MAN

By Dr. R. A. FILDES and Prof. HARRY HARRIS
Medical Research Council Human Biochemical Genetics Research Unit, The Galton Laboratory, University College, London, W.C.1

ADENYLATE kinase (AK), also known as myokinase, is a phosphotransferase (EC 2.7.4.3) which catalyses the reversible reaction:

$$2\ ADP \rightleftharpoons ATP + AMP$$

The enzyme has mainly been studied in muscle[1]. However, it is also known to occur in other tissues[2], and red cells in particular have been found to show considerable activity[3–5]. We describe in the present article a procedure for the detection of the enzyme after starch-gel electrophoresis, and report the results obtained with human red cell lysates and muscle extracts. It has been found that several isoenzyme components with adenylate kinase activity occur, and that there are also person to person differences in the pattern of components present. These differences are genetically determined.

Horizontal starch-gel electrophoresis was carried out at 10 V/cm for 4 h in the laboratory, using metal cooling plates with circulating tap water. Samples were examined at *p*H 7·0 using a discontinuous buffer system (gel buffer 0·005 M in histidine, bridge buffer 0·41 M in citric acid: both adjusted to *p*H 7·0 with sodium hydroxide). The inserts were made from Whatman No. 3 filter paper. Following electrophoresis the gels were sliced and then covered with a 0·75 per cent agar solution at 45° C made in 0·1 M *tris* buffer *p*H 8·0 and containing glucose 10 mM, magnesium chloride 20 mM, adenosine diphosphate (ADP) 1·0 mM, nicotinamide adenine dinucleotide phosphate (NADP) 0·4 mM, phenazine methosulphate (PMS) 0·012 per cent, tetrazolium salt MTT (ref. 6) 0·012 per cent, glucose-6-phosphate dehydrogenase (G6PD) 0·04 units/ml., and hexokinase 0·08 units/ml. The agar 'overlay' was allowed to set and then the gel was incubated at 37° C for up to 2 h. The reaction mixture was designed to locate AK according to the reaction sequence shown in Fig. 1. At the sites of AK activity ADP is converted into AMP and ATP. The ATP so formed reacts with glucose in the presence of hexokinase to produce ADP and glucose-6-phosphate (G6P). The latter is oxidized by G6PD to 6-phosphogluconate (6PG) with the concomitant reduction of NADP. The reduced NADP in the presence of PMS, which is thought to act as an electron carrier, causes the reduction of MTT to give a blue-coloured insoluble formazan which is thus deposited at the sites of AK activity.

Red cell lysates (prepared by mixing one volume of packed cells with two volumes of water) from a large number of different individuals have been examined by this procedure. Three distinct types of electrophoretic pattern have been recognized (Fig. 2), and they will be referred to as AK 1, AK 2–1, and AK 2. About 90 per cent of individuals in the English population have the AK 1 phenotype and about 10 per cent the AK 2–1 phenotype. AK 2 is very uncommon, and so far only a few individuals with this phenotype have been identified. In AK 1 two major components are seen. The more active of these does not migrate appreciably at *p*H 7·0, while the other is negatively charged and migrates towards the anode. Besides these, at least two, relatively much less active, components also occur and they migrate

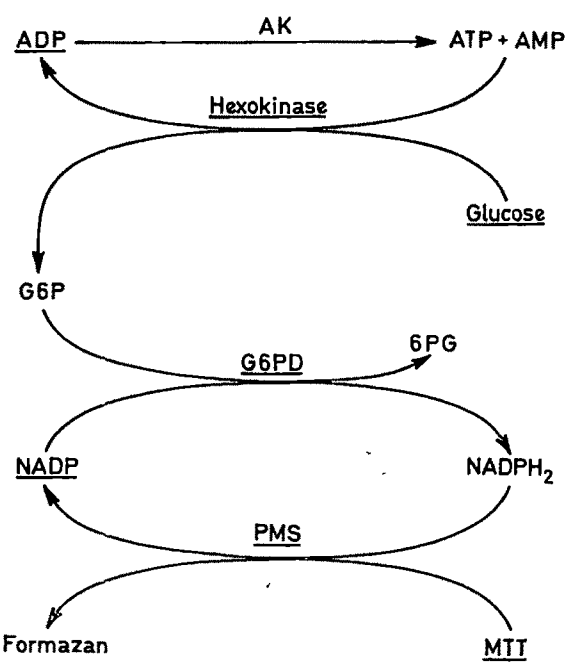

Fig. 1. Sequence of reactions for detection of adenylate kinase following starch gel electrophoresis. In this system ADP is used as substrate, and the other components underlined are contained in the reaction mixture

even more rapidly towards the anode. In AK 2–1 components with mobilities of each of those present in AK 1 are found. However, there is in addition a further major component which is positively charged and migrates towards the cathode. This component is somewhat less active than the component present on the origin, but more active than any of the anodically migrating components. In AK 2 most of the activity is concentrated in a single positively charged component which has the same mobility as the cathodically migrating component of AK 2–1. Other components with mobilities similar to those seen in AK 2–1 are also present, but they are relatively very much less active. Artificial mixtures of equal volumes of haemolysate of type AK 1 and AK 2 give an electrophoretic pattern indistinguishable from AK 2–1. It has also been shown using serially diluted haemolysates that the component on the origin and the main anodically moving component present in AK 2–1 are on the average appreciably less active than the components with similar mobility in AK 1.

Adenylate kinase in skeletal and heart muscle has also been examined by this procedure. The muscle samples were obtained *post mortem*. Extracts were prepared by homogenizing in an equal volume of water and, after centrifuging, diluting the supernatant 1 in 10 with buffer. All the zones of activity seen in the haemolysates were observed in the muscle extracts. Furthermore, the distinctive AK 1 and AK 2–1 patterns were found in muscle samples obtained from different individuals. In every case the AK phenotype observed in the muscle extract was the same as the AK phenotype found in red cells from the same individual. The muscle extracts utilized for electrophoresis were generally more active than the haemolysates, and they usually showed several additional weak zones of activity migrating relatively rapidly towards the anode. Similar zones have occasionally been observed with haemolysates.

Evidence that the zones of activity seen under these conditions are indeed attributable to adenylate kinase activity may be summarized as follows:

(1) If ADP is omitted from the reaction mixture none of the zones develops. Increasing the concentration of ADP in the reaction mixture up to at least 10 mM results in an increasing rate of development of the zones.

(2) The reaction catalysed by adenylate kinase is freely reversible and it has proved possible to detect the zones of activity using ATP and AMP as substrates instead of ADP. For this purpose a 0·75 per cent agar solution at 45° C made in 0·1 M *tris* buffer and containing ATP 1·0 mM, AMP 1·0 mM, reduced nicotinamide adenine dinucleotide ($NADH_2$) 0·3 mM, phosphoenolpyruvate (PEP) 1·0 mM, potassium chloride 0·1 M, magnesium chloride 0·04 M, lactic dehydrogenase (LDH) *c.* 1·0 units/ml., pyruvate kinase *c.* 0·1 units/ml., is poured over the starch gel, allowed to set and then incubated for up

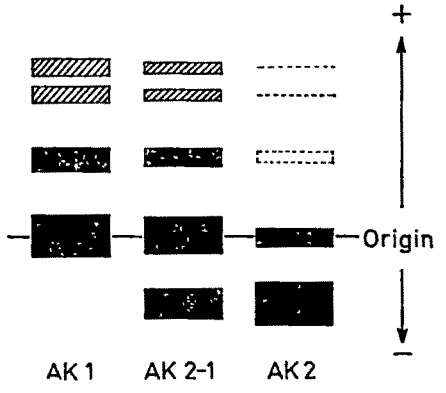

Fig. 2. Diagram showing electrophoretic patterns of three different human adenylate kinase phenotypes

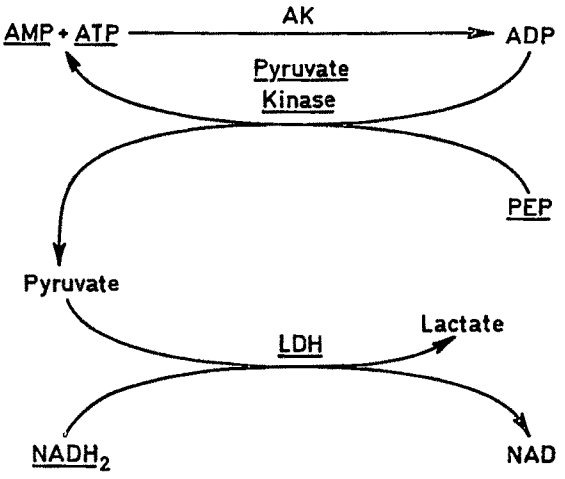

Fig. 3. Sequence of reactions for detection of adenylate kinase following starch-gel electrophoresis. In this system ATP and AMP are substrates, and the other components underlined are contained in the reaction mixture

to 2 h at 37° C. This reaction mixture was designed to locate AK according to the reaction sequence shown in Fig. 3. The ATP and AMP react at the sites of AK activity to give ADP, which is then phosphorylated by PEP under the action of PK to yield ATP and pyruvate. The pyruvate is reduced by LDH with the concomitant oxidation of $NADH_2$ to form lactate and NAD. The sites of AK activity appear as zones of absorption (NAD) on a fluorescing background ($NADH_2$) when the gels are examined in ultra-violet light (Hanovia lamp with peak transmission 3660 Å units). Despite the quite different reagents and reaction system utilized in this procedure, the patterns of activity observed were the same as those found with the procedure using ADP as substrate.

(3) It has been reported[7] that AK is noticeably stable to acid conditions. We have found that red cell lysates adjusted to *p*H 2·0 with 2 N hydrochloric acid and then after 10 min at room temperature neutralized with 2 N sodium hydroxide still gave the same AK electrophoretic pattern. Other enzyme electrophoretic patterns such as lactic dehydrogenase and 6-phosphogluconate dehydrogenase were destroyed by this treatment, which also resulted in a heavy precipitate of denatured haemoglobin.

(4) A comparison has been made between a purified crystalline adenylate kinase preparation made from rabbit muscle obtained commercially, and a crude rabbit muscle extract made by homogenizing the muscle in an equal volume of water. The crude extract diluted 1 in 10 with gel buffer was subjected to starch-gel electrophoresis under the standard conditions side by side with a suitable dilution of a crystalline AK preparation. Identical patterns of activity were obtained. There were at least three zones and they had the same mobilities in the two preparations. The mobilities were different from those observed using human material.

Haemolysates from 960 unrelated English people have been examined. Among 540 males there were 60 (11·1 per cent) who were AK 2–1, and among 420 females there were 35 (8·3 per cent) who were AK 2–1. The difference between the sexes is not statistically significant and one may conclude that AK 2–1 occurs with a frequency close to 10 per cent in the general population. Only one

Table 1. AK Phenotypes among 136 Children of 54 Matings where one Parent was AK 1 and the Other AK 2–1

Parents		No. of matings	Children				Total
			AK 1		AK 2–1		
Father	Mother		Males	Females	Males	Females	
1 × 2–1		28	23	17	14	16	70
2–1 × 1		26	17	15	17	17	66
		54	40	32	31	33	136

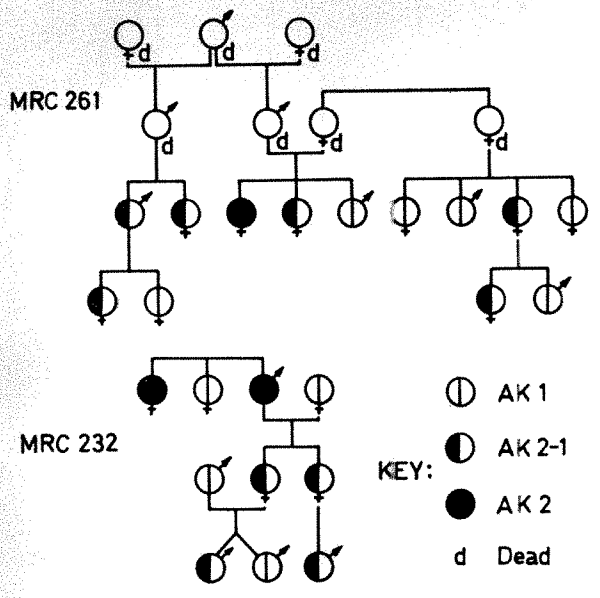

Fig. 4. Pedigrees of two families in which the uncommon phenotype AK 2 was found to occur

instance of AK 2 (a female) was observed in this population sample. Family investigations make it clear that these phenotypic differences are genetically determined. Table 1 summarizes the findings among the offspring of 54 matings in which one parent was AK 1 and the other AK 2–1. Among the 136 children tested, 72 were AK 1, 64 AK 2–1 and there were no examples of AK 2. This is in striking contrast to the findings in 62 families where both parents were AK 1. Here all the 141 children tested were also AK 1. These results and also the segregation patterns in several quite extensive pedigrees suggest that the differences may be attributed to a pair of autosomal allelic genes (AK^1 and AK^2), AK 1 individuals being homozygous (AK^1AK^1) and AK 2–1 individuals heterozygous (AK^1AK^2). If this were so the gene frequency of AK^2 in the English population should be about 0·05, and the homozygote AK^2AK^2 might be expected to occur in about 1 in 400 of the population. It seems probable that the uncommon phenotype which we have designated AK 2 represents the homozygous genotype AK^2AK^2. Although only one individual with this phenotype was encountered in the series of 900 unrelated individuals mentioned here, three other examples of the phenotype have been encountered in the course of our family investigations. The relevant parts of the two pedigrees in which they occurred are shown in Fig. 4. In both these families the difference between the AK 2 and AK 2–1 electrophoretic patterns was quite clear cut and there was no difficulty in differentiating the two phenotypes. The segregation of the phenotypes in these families is clearly consistent with the hypothesis that AK 2 individuals are homozygotes AK^2AK^2. However, further family data are obviously needed on this point.

The preparations of adenylate kinase, glucose-6-phosphate dehydrogenase, hexokinase, pyruvate kinase and lactate dehydrogenase were obtained from Boehringer Corporation (London), Ltd.

PROBABLE *in vivo* ORIGIN OF MULTI-NUCLEATED GIANT CELLS FROM CIRCULATING MONONUCLEARS

By Dr. T. GILLMAN and L. J. WRIGHT

Agricultural Research Council, Institute of Animal Physiology, Babraham, Cambridge

LEWIS[1] demonstrated that, in culture, multi-nucleated giant cells could be formed by fusion of blood monocytes—a view supported by many other workers since (see reviews in refs. 2 and 3). Willis[4] states crisply the opinions at present most widely held regarding some of the possible sources of giant cells *in vivo*, namely: "Some workers believe that foreign-body giant cells may develop, not only by fusion, but also by amitotic nuclear division of macrophages, but from the appearances observed it is clear that fusion is their main, if not their only, mode of formation". Objective proof of these views is, however, still lacking.

During the course of recent radioisotope investigations of the histo- and cyto-genesis of fibrous tissue in wounds and around implanted foreign bodies, evidence emerged that at least one type of multi-nucleated giant cells, related to fibrosis around foreign bodies, is formed by fusion of circulating blood mononuclears (that is, lymphocytes and/or monocytes) after they have emigrated into injured tissues.

The experiments were of two types, namely: (1) tritiated thymidine was injected intravenously into adult rats either at 18 h or at both 18 and 5 h before wounding and implanting foreign bodies (Millipore filters or polyvinyl sponges) subcutaneously and/or intraperitoneally; the foreign bodies were removed at various times from 1 to 14 days after implantation; (2) previously unlabelled rats, carrying identical types of excised wounds and implanted foreign bodies (intraperitoneally or subcutaneously), received, only post-operatively, a single intravenous injection of tritiated thymidine just 2 h before killing and removal of the wounds and foreign bodies. In all the experiments, touch or imprint preparations were made of portions of each of the excised wounds and foreign bodies[5]. To avoid chemiograms, it was found necessary to fix the imprints in C.P. methanol for 24 h. Then, after coating with liquid emulsion and exposure for 14–92 days, the imprint preparations were developed and stained by modifications of the Giemsa method originally described by Speirs *et al.*[6]. Autoradiographs were also made of serial paraffin sections of these same wounds and foreign bodies. The imprint preparations provided the most striking and reliable cytological pictures because of minimal cell shrinkage; Giemsa staining also permitted direct morphological comparison of the cytology of cells in the imprints with those seen in smears of the bone marrow and circulating blood prepared by accepted standard haematological methods and treated in the same way as tissue imprints. On the other hand, autoradiographs of the sections permitted both precise localization of all labelled cells and determination of their relations to pre-existing and newly formed vessels and fibrous tissue.

The results of these two sets of experiments were different although complementary. Multinucleated giant cells, containing 5–20 nuclei, were commonly seen in imprints and sections, and appeared as early as the third

post-operative day. Those multi-nucleated giant cells, found in the rats which had received isotope only prior to the operation, had many of their nuclei labelled (Figs. 1, 3 and 4). The same cells from animals flash-labelled only post-operatively, that is, just 2 h before killing, had completely unlabelled nuclei (Figs. 2 and 4).

Volkman and Gowans[7,8] showed clearly, in Rebuck-type skin windows, that labelled cells, which they named macrophages (whether or not they contained phagocytosed material), appeared in large numbers 24 h after operation only in rats that had received isotope 18–24 h pre-operatively. We have confirmed and extended these observations by showing that, within the first 1–4 days post-operatively, the greatest number of labelled mononuclear cells is obtained in wounds and implants by injecting rats with tracer 18–24 h before operation. By giving two pre-operative isotope injections, that is, at 18 and 5 h before operations, we could label between 60 and 80 per cent of the mononuclears found 24–48 h post-operatively in excised wounds and around implants.

There seems no reason to doubt that these lymphocytes and monocytes, in the inflamed and fibrosing tissues, were derived from the blood, especially since, at the time of operation and of killing, relatively few cells were labelled in the untraumatized connective tissues in comparable sites in the same rats. Many labelled lymphocytes and monocytes (5–15 per cent), as well as granulocytes, were consistently seen in the blood smears taken from these rats.

'Round cell' (mononuclear) emigration is a recognized sequel to the initial neutrophil infiltration seen in the early stages of any inflammatory response, including that preceding fibrosis in wounds and around foreign bodies. The fact that not all nuclei in the giant cells were labelled in rats injected pre-operatively with tritiated thymidine is to be expected, since 20–40 per cent of mononuclears in skin windows[7,8] and infiltrating injured tissues, in our experiments, were unlabelled.

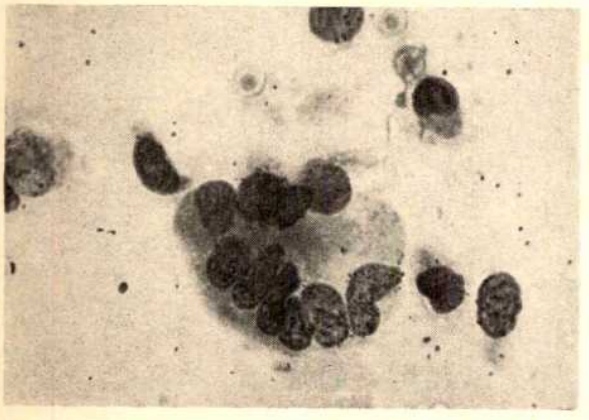

Fig. 1. Multi-nucleated foreign body giant cell and several round cells in an imprint of a 4-day-old subcutaneous sponge from a rat that had received 1 μc. per g body-weight of ^{3}H-thymidine intravenously at 18 and 5 h before operation only. Note clear labelling of at least two giant cell nuclei and of several of the round cells. Autoradiograph, Giemsa counterstain (× *c.* 703)

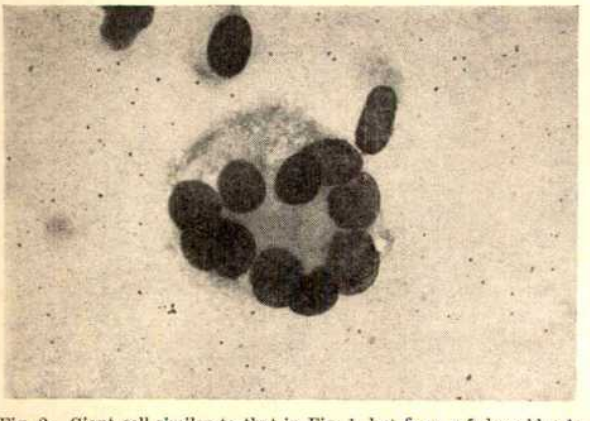

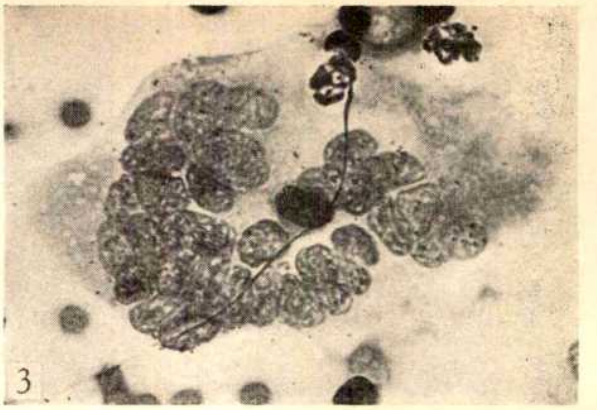

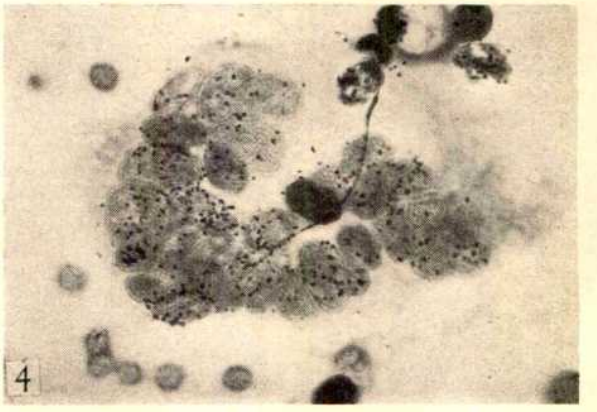

Fig. 2. Giant cell similar to that in Fig. 1, but from a 5-day-old subcutaneous sponge from a rat that received one injection of the same dose of label but only 2 h before death. No nuclei labelled. Autoradiograph, Giemsa counterstain (× *c.* 703)

Figs. 3 and 4. A very large giant cell from another rat injected once only, 18 h before operation with the same dose of isotope. These two figures, of the same cell, at two different levels of focus, show how many nuclei were labelled. Note also label in nuclei of adjacent neutrophils. The findings indicate formation of giant cells by fusion of labelled round cells. Autoradiograph, Giemsa counterstain (× *c.* 703)

The total absence of nuclear label in *any* of the nuclei of giant cells, in rats injected only post-operatively, that is, 2 h before being killed (Figs. 2 and 4), suggests that these nuclei were not synthesizing DNA. This fact, taken in conjunction with the labelling of some, but not all, giant cell nuclei in rats injected pre-operatively (Figs. 1 and 3), indicates that multi-nuclear cells were probably derived by fusion of both labelled and unlabelled local or, more likely, emigrated blood mononuclears.

Such giant cells, with a proportion of their nuclei labelled, were frequently found even 14 days after the operation, and hence 14 days and 18 h (or 14 days and 5 h) after the last pre-operative injection of isotope.

Shelton and Rice[9] described the presence, within histiocytes, of many lymphoma cells cultured *in vivo* in 'Millipore' chambers. In fixed material, such histiocytes could, in all probability, have been taken to be one type of multi-nucleated giant cells. It is also possible that, in our experiments, the presence of many labelled nuclei within a single giant cell could also have arisen by 'ingestion' of labelled blood lympho- or mono-cytes by tissue macrophages around the foreign bodies. It is interesting to note that, as shown in Figs. 1, 3 and 5, the size and other characteristics of the nuclei of the giant cells indicated that they were primarily lymphocytic rather than monocytic in origin. This was especially so in the subcutaneous giant cells. In the peritoneum, however, the giant cells were either attached to the peritoneal

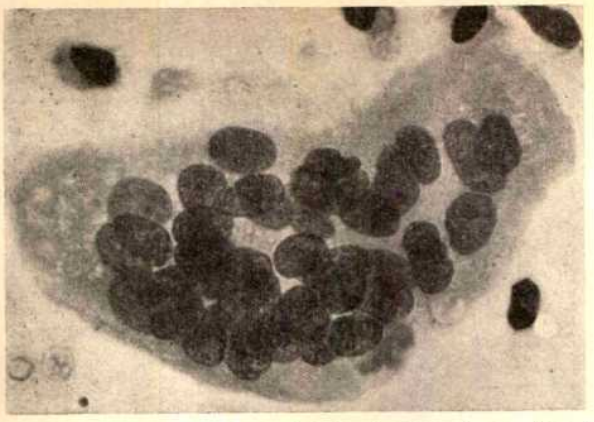

Fig. 5. Another very large giant cell, similar to that in Figs. 3 and 4 but in an imprint from a 7-day-old sponge from a rat injected with isotope only 2 h before death. Note, again, absence of any nuclear label indicating probable absence of active DNA synthesis during genesis of the many nuclei in this cell which was therefore probably formed by fusion of unlabelled round cells. Autoradiograph, Giemsa counterstain (× *c.* 703)

implants or were floating freely in the peritoneal fluid; they often contained large bi-lobed nuclei reminiscent of monocyte nuclei. Similar monocytoid (or paramonocytic)[5] giant cells, often resembling Reed–Sternberg cells, were a feature of the lymphomata produced in rats treated chronically with trypan blue[10,11]. These cells, also, may well have been derived from the circulating 'polymorphonuclear type' blood monocytes so common in these rats[11,12] and in which lympho- and mono- as well as erythrophagocytosis was shown to be a consistent finding in lymphoid tissues and liver.

These observations from our labelling experiments would seem to leave little doubt that at least the foreign-body-type multi-nucleated giant cells seen in these experiments were derived from previously labelled blood mononuclear cells either by their fusion, once they had emigrated into tissues, or through their being phagocytosed by locally resident macrophages. Our findings that, during the first 3 days post-operatively, a far higher percentage of infiltrating mononuclears were labelled if rats were injected with isotope many hours before operation than when isotope was given post-operatively confirm Volkman and Gowans's reports. However, we have here extended their observations to show that, once they have entered injured tissues, many of these labelled inflammatory cells may remain there for days, or even for 2 weeks post-operatively, where, in appropriate circumstances, they may fuse to form foreign body giant cells. The further implications of these findings for the possible origins of fibroblasts, as well as giant cells, has been discussed elsewhere[13,14].

VARIABLE AND INVARIABLE COMPONENTS OF THE ANTICOAGULANT FRACTION OF INCUBATED FIBRINOGEN

By Prof. E. TRIANTAPHYLLOPOULOS and Prof. D. C. TRIANTAPHYLLOPOULOS

Department of Physiology, University of Alberta, Edmonton, Canada

TRIANTAPHYLLOPOULOS[1] and Niewiarowski and Kowalski[2] showed independently, and it was later verified by others, that the breakdown products of fibrinogen possess anticoagulant properties. Most of the anticoagulant activity is exhibited by the protein which is precipitated between 25–50 per cent ammonium sulphate saturation. Since this fraction was originally isolated from solutions of incubated (spontaneously lysed) fibrinogen, it was called the anticoagulant fraction of incubated fibrinogen (AFIF)[3]. In 1962 we showed that AFIF can be separated by continuous-flow paper electrophoresis into two main sub-fractions which we found able to prolong the thrombin clotting time of intact fibrinogen to the same extent[4]. We later demonstrated that in human AFIF the larger of these sub-fractions is 70 per cent thermolabile, while the smaller is completely thermostable[5]. Since, however, both the thrombin time prolonging effect[6] and the thermoresistance[5] of AFIF have been shown to vary considerably with the length of the incubation of the parent fibrinogen solution from which a sample is isolated, it became necessary to investigate the effect of incubation on the activity and thermosensitivity of each electrophoretic fraction and estimate the extent to which each of these constituents is responsible for the variations observed with unfractionated AFIF preparations.

Human fibrinogen was isolated from outdated Red Cross plasma by saturation to 25 per cent with ammonium sulphate and reprecipitation of the protein by 50 per cent saturation with sodium chloride, as described earlier[6]. Bovine fibrinogen was prepared by the method of Laki[7]. Only preparations with a clottability of at least 92 per cent (human) or 84 per cent (bovine) were used.

Solutions of human fibrinogen at 10 mg/ml. in physiological saline (8·5 per cent w/v), buffered to *p*H 7·4 with 0·025 M imidazole and containing 0·028 M sodium citrate, were sterilized by passing them through Seitz filters and were incubated at 37° C. Bovine fibrinogen solutions in 0·3 M potassium chloride similarly buffered and citrated were digested at 37° C by a streptokinase-activated human fibrinolysin preparation (Thrombolysin) which was added at 0·12 casein and 60 casein activator units/ml. of final solution. As soon as each of the fibrinogen solutions became completely unclottable by thrombin (human fibrinogen was lysed spontaneously within 3–5 days, that of bovine origin within 30–80 min), aliquots of 60–100 ml. were removed at various intervals and fractionated with ammonium sulphate. Pancreatic trypsin inhibitor ('Iniprol' of the Choay Laboratories, Paris) was added to each fraction at a final concentration of 100 anti-Schwert–Takenaka[8] units per ml. before fractionation. The 25–50 per cent precipitates (AFIF preparations) from the successive samples were collected and an aliquot of each was subjected to either continuous-flow paper[4] or column electrophoresis. In the latter case, the Porath electrophoresis apparatus 3340 of the L.K.B. Co., Stockholm, was used. Munktell's cellulose powder especially developed for zone electrophoresis was pur-

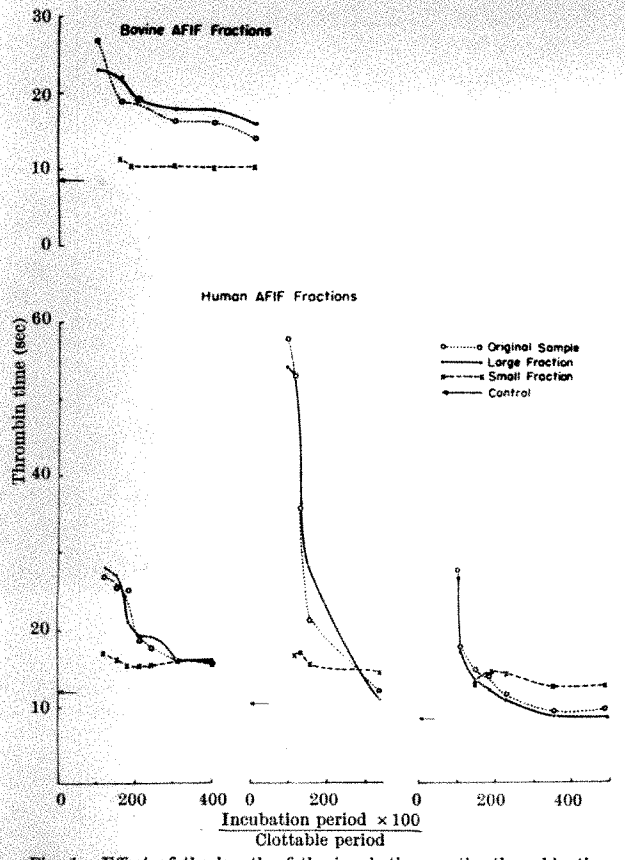

Fig. 1. Effect of the length of the incubation on the thrombin time prolonging ability of the main electrophoretic fractions of AFIF. The concentration of each fraction was adjusted to 4 and that of fibrinogen to 2 mg/ml. Thrombin times were determined at room temperature (25° C)

chased from Grycksbo Paperback A.B., Sweden. The buffer was veronal 0·02 M, *p*H 8·6. The sample (3–5 ml. at 40–70 mg/ml.) was stained with bromphenol blue and dialysed against 3–4 h changes of the veronal buffer under continuous stirring, before electrophoresis. The current was applied at 17 m.amp and ≃ 560 V until the blue-coloured band reached the bottom of the column (15–18 h). The flow rate of the eluting buffer was adjusted to one drop/10 sec and the fractions were collected at 20-min intervals. All operations were carried out at 2°–4° C. The absorption of each fraction at 280 mμ was measured in a Beckman *DB* spectrophotometer and the protein content was calculated from a curve which was prepared with AFIF solutions of known concentration. The protein pattern was the mirror image of that obtained with continuous-flow paper electrophoresis[6] since the most electro-negative components emerged from the column first. The central fractions belonging to each main peak were pooled together and concentrated by lyophilization. The dry powders were dissolved in saline and dialysed against it until free of veronal (no absorption at 240 mμ). Their effect on the thrombin time of intact fibrinogen was tested as described in an earlier publication[6].

Thrombin time prolonging effect of the electrophoretic fractions as a function of the incubation stage. Seven series of experiments were performed, five with human and two with bovine AFIF fractions. Separation of bovine AFIF into fractions under the conditions of these experiments was never so good as that obtained with human preparations. In the majority of cases it was not possible to isolate small-fraction material free of large-fraction contamination in quantities sufficient for these investigations and these experiments were not taken into account. The incubation period of each sample was expressed as a percentage of the clottable period (initial stage of incubation during which the fibrinogen was still clottable by thrombin) in order to facilitate the comparison of the results from experiments with different degrees of fibrinolytic potency. The prolongation of the thrombin time exerted by the large fraction of human AFIF (Fig. 1) was high at the beginning of unclottability (when separation into fractions could first be obtained) but decreased considerably during advanced stages, following the same pattern which the original non-electrophoresed sample exhibited. The inhibition obtained hy the small fraction was much lower and changed little with incubation. Due to the progressive decrease in the activity of the large fraction, there were instances where this fraction was more, equally or in rare cases less active than the small fraction. The results obtained with the two series of bovine fractions (Fig. 1, upper part) indicate that the activity of the large fraction of these preparations was similarly reduced during advanced stages. However, the reduction was not as great as with human specimens and this fraction seemed to remain significantly more inhibitory than the smaller one at all stages. Some of the large peak fractions which were obtained from samples isolated at about the end of the period during which clotting could take place showed a lower antithrombic effect than their parent non-electrophoresed preparations, although the opposite was expected. This indicates that the large peak fractions of this period are labile and can lose part of their activity during electrophoresis, lyophilization or dialysis.

Thermosensitivity and relative concentration of the electrophoretic fractions of AFIF as a function of the incubation period. Aliquots of the two fractions were heated in a water bath at 60° C for 15 min. The precipitates were removed by centrifugation and the protein content of the supernatants was determined together with the concentration of an unheated aliquot of each preparation by Kingsley's biuret method for total protein[9]. The thermostable protein was then calculated as a percentage of the amount present before heating. Small peak fractions (upper half of Fig. 2) were found to remain completely thermoresistant throughout incubation. The resistance of the large peak moiety (middle left of Fig. 2), however, and the relative concentration of the small

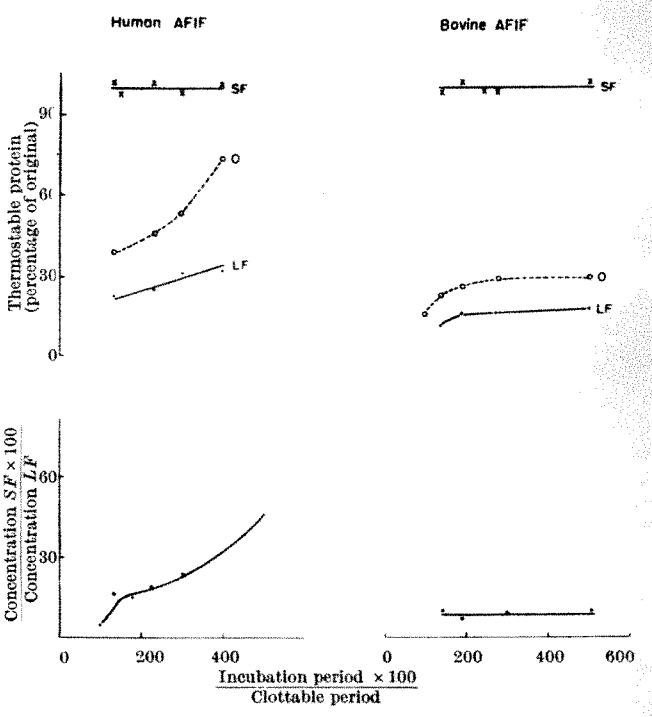

Fig. 2. Effect of the incubation period on the thermoresistance and relative concentration of the electrophoretic fractions of AFIF. The thermostable protein is expressed as a percentage of the protein concentration of the unheated samples. *SF*, Small fraction; *LF*, large fraction; *O*, original sample

fraction in human AFIF (lower left of Fig. 2) seemed to increase appreciably with incubation. One group of experiments with bovine fractions indicated that: (*a*) the stability of the large fraction of these preparations increased very little with incubation; (*b*) the ratio of the two fractions remained constant after 140 per cent of the clottable period. (Small fractions from bovine AFIF were never obtained at earlier periods under the conditions of these experiments.) So far as the ability of the heated fractions to prolong the thrombin time was concerned, the small fraction retained all its activity throughout, while the larger one was completely inactivated, for all practical purposes, at all stages.

It becomes obvious from the results of these experiments that both the increase in thermoresistance[5] and the reduction of the ability of AFIF preparations to prolong the thrombin time during advanced stages of incubation[6] are the result of the same factors: (*a*) appearance and gradual increase in relative concentration of the resistant, less active small fraction; (*b*) change in the quality of the larger fraction with increasing incubation. The latter factor is probably the most significant considering the higher relative concentration of the large fraction, especially between 100 and 200 per cent of the period during which clotting could take place when the sharpest changes in the activity and thermoresistance of AFIF occurred. Both the change in the quality of the large peak and the increase in the concentration of the small peak are minimal with bovine preparations but quite pronounced with human samples: this explains the greater variability of human AFIF[5,6].

PERCEPTION OF MOVEMENT BY THE CRAB

By Dr. G. A. HORRIDGE and P. R. B. SHEPHEARD
Gatty Marine Laboratory and Department of Natural History, University of St. Andrews

PERCEPTION of movement describes, in essence, a relation which is derived from two successive intensity changes at nearby points in the visual field. When a contrasting edge moves, a simple means of determining the movement would be to remember the old position and compare it with the new one in a system containing an absolute spatial representation of the retina. The following experiments on the crab *Carcinus* suggest that, in this animal, this may well be an important part of the mechanism for the perception of slow movement.

The eyes of a crab are on stalks and normally they will follow the movement of a striped drum placed around the animal. Over a range of drum speeds the eye moves more slowly than the drum, leaving a residual slip speed which maintains the stimulus for the eye movement[1]. The percentage following, defined as the ratio of eye speed to drum speed multiplied by a hundred, varies with the speed of movement and is low for very slow or very fast shifts of the drum. With the crab out of water, the eye is capable of following drum movements down to about 0·002 degrees/sec, that is, several times slower than the hour hand of a clock, which is 0·0083°/sec.

A crab was placed with one eye at the centre of a striped drum. The movements were recorded by a photocell activated by a narrow infra-red beam and the other eye was kept covered. In our experiments, the drum radius was 8 in., and the repeat pattern of the stripes subtended 28·7° at the eye, but the details of the pattern, so long as it is large, or its exact regularity and illumination are of little importance for the experiment described here. The crab was left undisturbed for 15 min and the light was then turned out. Movements of the drum now produced no response. During an adjustable period in darkness the drum was moved through a controlled angle. When the light was switched on again, the eye swung to a new position by moving in the direction in which the drum had been turned. In all experiments, 3 min was allowed for the eye to reach its new equilibrium position. It was possible to show a directional response to a movement of 0·5° over a dark period of 2 min or of an angle of 1° over 15 min. A response to 1·5° over 40 min was achieved. Lower thresholds and longer times could not easily be reached in single trials because the eye moved and drifted in the dark, and switching on the light suddenly after long periods in the dark may have caused flicking or retraction of the eye or leg movements so that it was necessary to discard the result.

Results for different drum movements are shown in Fig. 1. The ordinate percentage following is the ratio of eye movement to drum movement, expressed as a percentage. When the light was switched on, the drum was stationary, so that during the eye movement the stripes moved across the eye as if the drum had been moving in the opposite direction, but this did not appear to inhibit the actual percentage following so much as the time taken to reach the final position.

Movement of the drum in the dark by one black–white repeat distance caused no response, showing that it was the stripes which were perceived. Movement through half this angle, so that white replaces black, also caused no response. In this instance no clue as to the direction of the movement was given. It is curious that for some degrees on each side of this position the direction of the slope of the curve in Fig. 1 suggests that a black–white edge is confused with a white–black one. Large angles cannot be tested with a striped drum, but when a single black–white edge was moved around the eye in the dark, responses to much larger angles occurred when the illumination was resumed. For angles up to 180° the results are shown in Fig. 2, for a period of 1 min in the dark. The actual angle of the response increased for rotations up to about 160°, showing that the crab took a measure of these large rotations. It seems most unlikely that integration is limited to subjacent ommatidia. The percentage following is low, as it always is for a continuously illuminated single contrasting edge, and actual eye movements are less than 1°.

As the period of intervening darkness was lengthened, percentage following by the eye progressively fell off. Results up to 10 min are shown in Fig. 3, but a directional response could still be obtained when a movement of a few degrees was made before the light was switched on

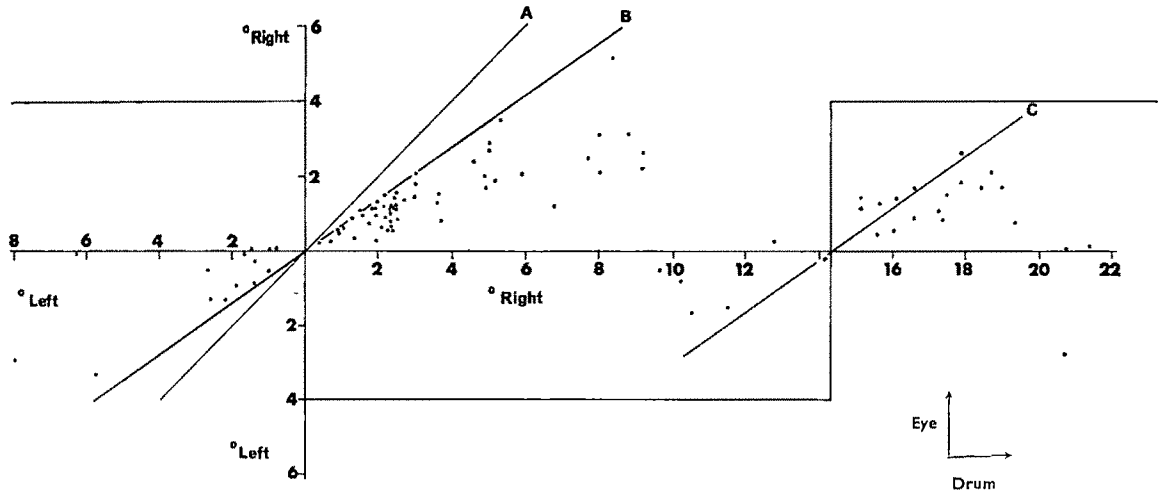

Fig. 1. Eye movements, to right and left plotted vertically, as a response to drum movements which were made during a period of darkness of 1 min through different angles as plotted horizontally. The line *A* shows where eye movement would equal drum movement, which is never realized. The line *B* shows the maximum observed percentage following for a 1-min period of darkness (69 per cent). The line *C* is drawn with the same slope through the point at the half period of the pattern

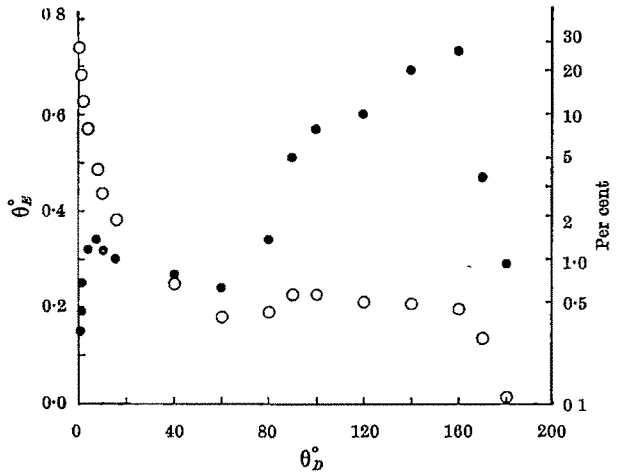

Fig. 2. Responses to a movement, which is made during a dark period of 1 min, of a single black–white edge through various angles θ_D up to 180°. The solid circles, with linear scale on the left, show actual angles θ_E of the eye response, averaged for left and right movements. The open circles, with logarithmic scale on the right, show the ratio of eye movement to drum movement (converted to a percentage)

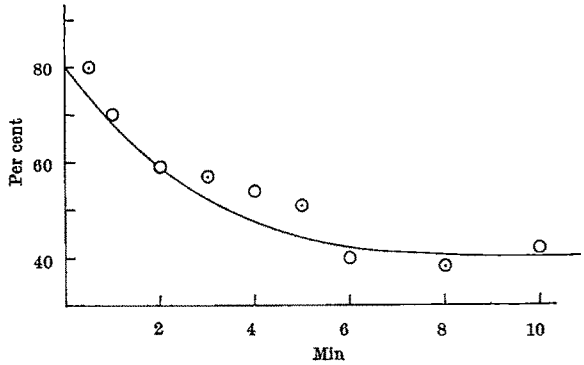

Fig. 3. The percentage following by the eye of a striped drum which is re-illuminated after different periods of darkness as shown, during which time the drum is moved through any angle up to 5°. The curve shows the exponential decay from 80 per cent to 40 per cent with a time constant of 150 sec

after a period of 40 min in the dark. Quantitatively consistent results, however, were not obtained over periods in the dark of longer than 10 min.

In a previous paper[1], it was shown that the eyestalk of the crab would give a directional response which was a reasonably accurate measure of an observed drum speed comparable with that of the Moon across the sky. Besides eliminating models of the mechanism of movement perception which have small time constants, the present results show that the crab can perceive movements at this speed of a contrasting object which is obscured for up to 10 min.

A second experiment which we carried out showed that movements of large contrasting areas rather than their edges predominated in governing a response, so that the response could be in a direction opposite to that in which a continuously illuminated edge moved.

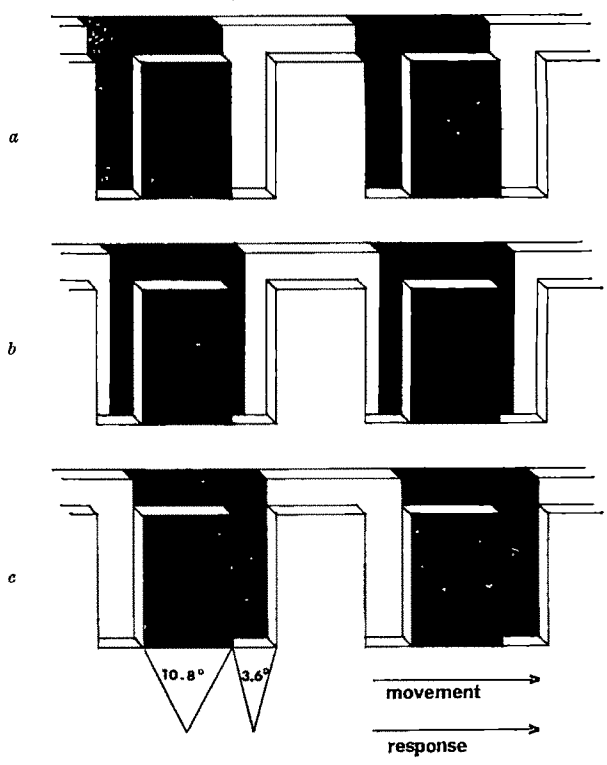

Fig. 4. An outer striped drum moves to the right around the outside of a fixed drum which has slots between each white and black stripe. All edges seen by the crab move to the right and the response is in that direction also. The drums are drawn in three dimensions for clarity

An outer movable drum of equal stripes closely surrounded an inner movable drum which was slotted as well as striped. Both drums had repeat patterns which subtended the same angle at the eye, in our case 28·7°. The first arrangement is shown in Fig. 4. Under continuous illumination the outer drum was moved from position (*a*) to position (*c*) in a controlled period of time, passing through position (*b*). Each black stripe of the inner drum thus lost a band of black on its left and gained one on its right. The time over which the movement occurred was varied between 1 and 900 sec, and the angle of response by the eye in the same direction as the outer drum is shown in Fig. 5*A*. After the end of the movement, 3 min was allowed for the eye to reach equilibrium. Clearly, the movement was well perceived over a wide range of drum velocity.

The experiment was repeated with the black and white stripes of the outer drum reversed in position (Fig. 6). While illuminated, the outer drum moved from (*a*) to (*c*) in the same range of controlled periods. Each inner black stripe now had a diminishing black area moving away from its right and a different growing black area moving towards its left side. At the half-way stage (*b*) there was a symmetrical situation with half the edges moving to the right and half stationary. The curious fact was that, from the beginning, the response was in the opposite direction to the movement, although in other experiments the movements of edges which were separated by these distances were clearly resolved with a sensitivity down to 0·1° of movement.

The eye movements, in the opposite direction to the drum movements, were plotted as percentage following in Fig. 5*B*. In the range 1–10 sec for a 3·6° movement, the form of the response and the percentage following was the same as in Fig. 5*A*; indeed, the human eye would respond to instantaneous movements of Figs. 4 and 6 in the same way as did the crab. The experiment of Fig. 6 showed that each of the inner stripes together with its adjacent slot could be considered as a unit. While the outer drum moved to the right, the 'centre of whiteness' of the white inner stripes, and the 'centre of blackness' of the black inner ones moved at an equal rate to the left. At low speeds, the eye of the crab started off in the opposite direction to the outer drum with a short latency as the drum began to move. Evidently, therefore, it followed the centres of large contrasting areas and had no need to compare Fig. 6*c* when it came to rest with the memory of Fig. 6*a*, although this must have been the mechanism at high drum speeds. At low drum speeds the crab eye movements fell off in Fig. 5*B* more than in Fig. 5*A*, perhaps because the moving or stationary edges interfered with the response, or because the response depended on a memory which faded.

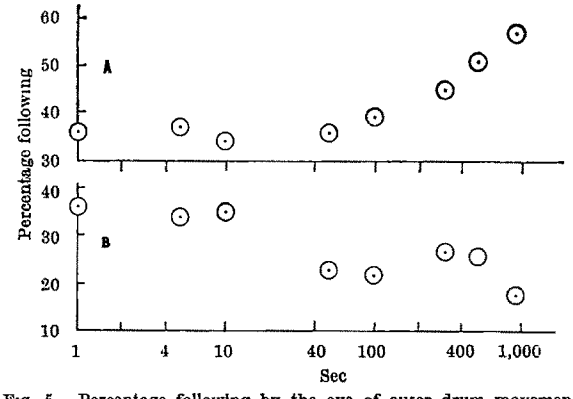

Fig. 5. Percentage following by the eye of outer drum movements occurring over different periods of time (*A*) Movements as in Fig. 4; (*B*) movements as in Fig. 6

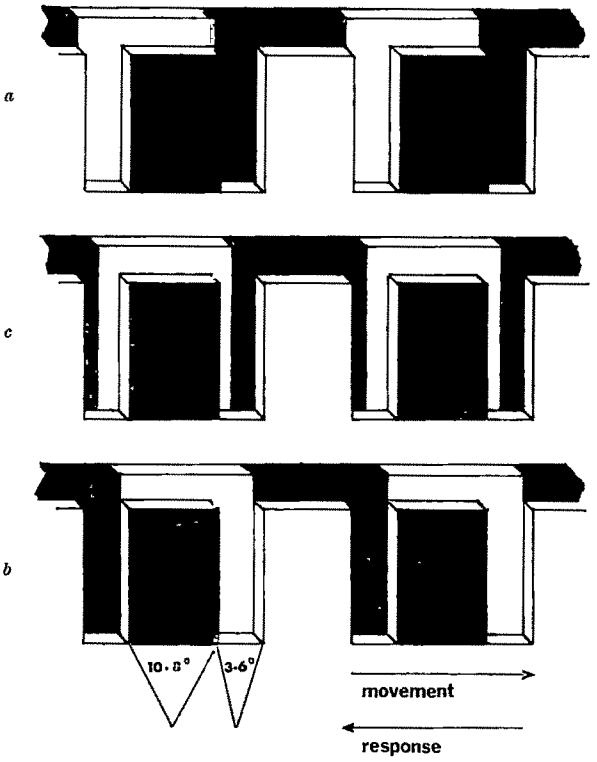

Fig. 6. As in Fig. 4, but with the black and white stripes of the outer drum reversed. Half the contrasting edges move to the right but the centres of the black and white areas (including all within the adjoining slots) move at an equal rate to the left, which is the direction of the eye response

Summarizing, our first experiment showed that the time could be long over which intensity changes were integrated before an inference of movement was made, and that intervening large changes in general illumination were of no consequence. The second experiment suggested that the eye follows not edges, but centres, of large areas. Both experiments were difficult to reconcile with present-day views on vision by the compound eye

INTESTINAL ABSORPTION OF PRALIDOXIME AND OTHER ALDOXIMES

By Prof. RUTH R. LEVINE

Department of Pharmacology and Experimental Therapeutics, Boston University School of Medicine, Boston University Medical Center, Boston, Massachusetts

AND

Dr. GEORGE M. STEINBERG

U S. Army Chemical Research and Development Laboratories, Edgewood Arsenal, Maryland

CORRELATIONS have been demonstrated between degree of lipoid solubility and rate of penetration of various substances across biological barriers[1], including the intestinal barrier[2]. These observations were used, initially, to make inferences concerning the nature of the biological barrier in terms of the penetration of organic compounds[1]. By circuitous reasoning, similar observations have been used to formulate the generalized con-

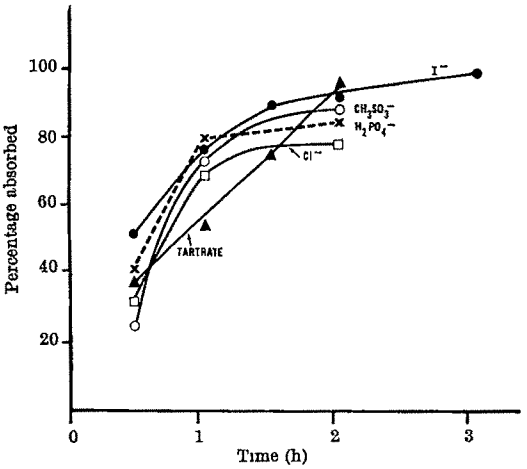

Fig. 1. Absorption of 2-PAM salts in the rat *in vivo* as a function of time. All compounds were administered to *in vivo* intestinal loops of rats in 0·5 ml. of a solution of 8×10^{-3} M concentration of 2-PAM (2-PAM-tartrate contains 2 moles of PAM to 1 mole of tartrate). ●, 2-PAM-I, ○, 2-PAM-CH_3SO_4; ×, 2-PAM-H_2PO_4; □, 2-PAM-Cl; ▲, 2-PAM-tartrate

clusion that organic compounds would readily traverse a barrier, such as the intestinal barrier, only if the compounds were lipophilic; as acids and bases in aqueous solution are involved in protonic equilibrium between a charged species which is considered to be lipophobic and an uncharged species which is considered to be lipophilic, this generalization was extended to exclude from the readily traversing compounds those which exist largely in the charged form at physiological *p*H (ref. 2). (*Note* 1. Various compounds, such as thiopental, aniline and salicylic acid, were judged lipoid soluble on the basis of chloroform/water partition coefficients of 2·6 to >100 and were found to be absorbed to 50 per cent or more from the small intestine; compounds, such as barbituric acid and sulphaguanidine, with chloroform/water partition coefficients of 0·008 to < 0·002, were judged lipoid insoluble and were absorbed to less than 5 per cent.) However, many strongly acidic compounds and strongly basic compounds, as well as some quaternary ammonium compounds, all of which exist entirely or almost entirely in the charged form at physiological *p*H, are known to be absorbed from the gastrointestinal tract, albeit inefficiently[3].

This article presents results of investigations of intestinal absorption of a number of mono- and *bis*-quaternary pyridinium aldoxime salts, including pralidoxime (2-formyl-1-methylpyridinium chloride oxime, 2-PAM). The mono-quaternary members of the group are unique among charged compounds of non-biological origin in their rapid and near-complete absorption from the small intestine.

The degree of intestinal absorption was determined *in vivo* using a single-loop preparation in non-fasted, male rats of the Sprague–Dawley strain, weighing 180–210 g (ref. 3). Each compound was injected quantitatively into the intestinal loop in a total volume of 0·5 ml. of experimental solution. At the end of an experiment the entire loop of gut and its contents were prepared for chemical analysis and determination of the quantity of unabsorbed aldoxime. Before any compound was used in the absorption studies, investigations were undertaken *in vitro* to determine whether or not any degradation of the compound occurred within the intestinal loop[3]. None of the compounds was found to be degraded; this permitted equating loss from the intestinal loop with amount absorbed from the loop.

The ultra-violet spectrographic method used for the determination of the various aldoximes was that of Creasey and Green[4], adapted for each different compound. The specificity of each adaptation was verified by ultra-violet spectral analysis of acid, neutral and alkaline solutions of compound present in the gut compared with corresponding standards. For each experiment, both reagent and tissue blanks were run and the spectrophotometric readings were corrected for these blanks.

The results of *in vivo* absorption investigations with five salts of 2-PAM are shown in Fig. 1. The percentages of absorption of the methanesulphonate, phosphate, chloride and iodide salt were not significantly different from each other (by Student's *t*-test) at any time-interval. However, the percentage absorption of the tartrate salt was significantly lower than that of the other four salts at 1 h and significantly lower than that of the iodide at 1·5 h; there were no significant differences in absorption among any of the salts at 2 h. Thus, 2-PAM tartrate was absorbed more slowly, although ultimately as completely as the other four salts.

To determine whether the observed difference in rate was specific for the molecular species, 2-PAM tartrate, or was the effect of the presence of the tartrate ion *per se*, absorption rates were measured for several combinations of 2-PAM iodide or tartrate with added iodide-ion or tartrate-ion. 1-h absorption periods were used for the latter investigations, since this was the time of greatest difference between the amount of absorption of the iodide and tartrate salts of 2-PAM. Fig. 2 shows the regression lines calculated for each of four different sets of experimental conditions. The calculations were made on the basis of individual values, that is, the percentage absorbed in 4–8 animals at each of five concentrations (between 0 and 64×10^{-3} M) of added tartrate or iodide-ion. All regression lines were found by analysis of variance to be significantly different from straight lines ($P < 0{\cdot}05$). The slope of each of the regression lines was significantly different from zero ($P < 0{\cdot}05$). The two lines of negative slope (*C* and *D*) represent the results of adding potassium tartrate to 2-PAM-iodide and 2-PAM-tartrate; the addition of potassium tartrate progressively

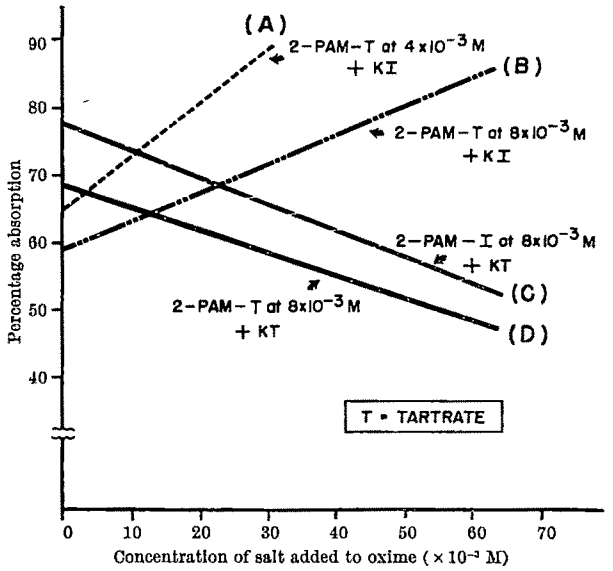

Fig. 2. Effect of added salt on absorption of 2-PAM-I and 2-PAM-tartrate in 1 h. Regression lines calculated for each set of conditions. All compounds were administered to *in vivo* intestinal loops of rats in 0·5 ml. of solution. Concentration of 2-PAM salts in terms of molarity of 2-PAM ----, 2-PAM-tartrate, 4×10^{-3} M, with added potassium iodide, —··—··, 2-PAM-tartrate, 8×10^{-3} M, with added potassium iodide, — — —, 2-PAM-I, 8×10^{-3} M, with added potassium tartrate; ———, 2-PAM-tartrate, 8×10^{-3} M, with added potassium tartrate

PARAMETERS OF REGRESSION LINES OF THE PERCENTAGE ABSORPTION OF 2-PAM ON CONCENTRATION OF SALT ADDED TO OXIME

$Y = bX + a$

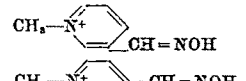
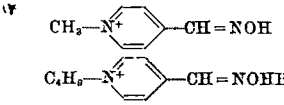
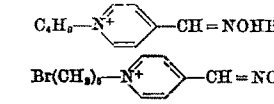
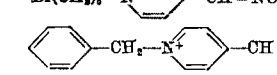
A	20	6·24 ± 2·24	64·1 ± 4·62
B	24	3·2 ± 0 956	58·8 ± 3·57
C	20	−3·22 ± 0 795	77·3 ± 3 59
D	24	−2 74 ± 1·21	68·2 ± 4·17

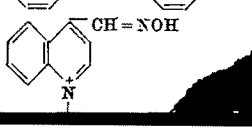
b, Slope of linear regression line; S_b, standard error of the slope; *a*, intercept of line on *Y* axis; S_a, standard error of the intercept; *n*, No. of animals











depressed the rate of absorption of both the iodide and tartrate salts of 2-PAM. In Fig. 2, the upper two lines (*A* and *B*) represent the results obtained on addition of potassium iodide to two different concentrations of 2-PAM-tartrate; the addition of iodide-ion progressively increased the absorption of 2-PAM-tartrate, the iodide-ion overcoming the adverse effect of tartrate. The positive slopes of lines *A* and *B* were found to be insignificantly different from each other, as were the negative slopes of lines *C* and *D*. This latter finding coupled with the relative positions of the lines suggests that: (1) there is a common ion effect of tartrate acting independently to adversely affect, in some unknown fashion, the transfer system for 2-PAM, and (2) there is a competitive effect of iodide-ion to overcome the effect of tartrate-ion. The slopes of regression lines (not shown in Fig. 2) for the absorption of 2-PAM-iodide in the presence of increasing concentration of the common anion, iodide (administered as potassium or sodium iodide), were found to be insignificantly different from zero. Any influence of the presence of increased concentrations of inorganic cation was also eliminated from consideration since the addition of sodium or potassium chloride, at 64 × 10^{-3} M, had no effect on the absorption of 2-PAM-iodide. Therefore, the observed differences in rate of absorption of 2-PAM when it was administered as an iodide or tartrate salt can be directly related to the presence of the respective anion.

Investigations carried out to determine the effects of dicarboxylic and hydroxycarboxylic acids have shown that addition of succinate, malonate, lactate, malate and citrate did not alter the absorption of 2-PAM-iodide. Therefore, the effect of tartrate on the absorption of 2-PAM cannot be attributed to any fragment of its structure and would appear to be specific. In at least one other case, the presence of organic anions has been shown to influence the absorption of a quaternary ammonium compound: butyrate, propionate and acetate increased both final percentage and initial rate of absorption of the non-aldoxime, benzomethamine, from *in vivo* intestinal loops of rats[5].

The degree of intestinal absorption of other mono-aldoximes, in addition to 2-PAM, and of a number of *bis*-aldoximes also has been determined. The results of some of these investigations are summarized in Table 1. All the mono-aldoximes, including 3-PAM and 4-PAM, were extremely well absorbed. Time-course investigations with these compounds indicated that their absorption was like that of 2-PAM, that is, rapid initial absorption within the first hour and then a continuous decrease in rate between 1 and 3 h. On the other hand, the *bis*-aldoximes (including TMB-3) were incompletely absorbed compared with the mono-aldoximes. The total amount absorbed and rate of absorption of the *bis*-aldoximes were similar to those of another *bis*-quaternary ammonium compound, hexamethonium, that is, the rates of absorption of both the *bis*-aldoximes and hexamethonium were relatively constant over the 3-h period studied[6]. Partition coefficients were calculated for each aldoxime from the distribution of the compound after shaking an aqueous solution of the aldoxime, buffered at *p*H 6·5, with chloroform for 30 min at 22° C. Using this distribution as a model of lipoid solubility, all the aldoximes were judged to be lipoid insoluble since all the partition coefficients, in the chloroform/buffer system, were less than 0·002; in this system, no marked differences were noted among the various compounds[2] (see *Note* 1 above).

Table 1. Intestinal Absorption of Aldoximes in the Rat

All compounds administered to *in vivo* intestinal loops of rats in 0·5 ml. of a solution containing 8 × 10^{-3} M aldoxime

Structure	*p*K*a*	Percentage absorbed in 3 h: Mean ± standard deviation
 I-(3-PAM)	9·2	85 ± 3
 I⁻ (4-PAM)	8·5	90 ± 2
	8·1	70 ± 4
	8·3	59 ± 8

This investigation was supported in part by research grant *DA*-18-108-405-*cml*-902 from the Department of the Army and by research grant *B*1966 from the National Institutes of Neurological Diseases and Blindness of the National Institutes of Health, U.S. Public Health Service. A preliminary report of this work was presented at the autumn meeting of the American Society for Pharmacology and Experimental Therapeutics, San Francisco, [illegible]nia, in August 1963. In conducting the research the investigators adhered to the *Principles* [illegible]*eral Care* as established by the National

ANTI-FOULING COMPOSITIONS

By Dr. P. de WOLF
Central Laboratory, T.N.O., The Netherlands
AND
Dr. A. M. van LONDEN
Paint Research Institute, T.N.O., The Netherlands

DURING and immediately after the Second World War extensive programmes of anti-fouling research were carried out, notably in the United States and in the United Kingdom[1-3]. The results of the research, especially those of American investigators[1], have provided a fertile source of information on the economics of the fouling problem, the biology of fouling organisms, the chemistry and physics of anti-fouling paint ingredients, and the prevention of fouling on ships. The research also enabled an insight to be gained of the mechanism of action of anti-fouling compositions and the liberation of poisons from the films.

The theory, derived from the research, for the mode of action of anti-fouling compositions can be summarized as follows: (1) An anti-fouling composition (containing a copper compound as the poison) will prevent fouling so long as the leaching rate is greater than 10 μg copper/cm^2/day. (2) The liberation of poisons can be explained by assuming the existence of two types of anti-fouling compositions—soluble and insoluble-matrix types.

In practice, however, the fouling problem was not solved efficaciously. It has since been shown that the theory cannot be used to explain many of the phenomena[4,5] observed in the study of anti-fouling compositions.

The evidence presented in this article is considered to show the necessity of amending both parts of the theory.

A critical evaluation of testing methods for anti-fouling compositions used by American and British investigators shows that the usefulness of the results obtained is more limited than was originally thought.

The results of raft trials, for example, have a definite value, but only for comparative tests. The advantages are the controlled conditions of exposure and the accessibility of test panels. A disadvantage is that the ageing proceeds in a way which differs quantitatively and qualitatively from practice—on the hull of a ship[6]. This difference may be explained by the greater rate of flow of seawater along the hulls of ships compared with the flow at raft sites.

On the other hand, patch tests on hulls of ships also have disadvantages. Reproducibility is almost impossible since conditions of test vary from one ship to another, for example, weather conditions during application and drying of compositions, the substrate and its pre-treatment, sailing routes, speeds of ships, fouling organisms encountered [illegible] and the number of days spent in port. Inaccessib[illegible] the patches as soon as the ship is out [illegible] another disadvantage, and the environ[illegible] is not always conduc[illegible]

Laboratory tests[6,11] offer the possibility of obtaining quantitative data under carefully controlled conditions; an ideal test should lead to a quick evaluation of the potential behaviour of a composition. A suitable method would consist of accelerated ageing preceding a biological method for an evaluation of the remaining anti-fouling action. The first requisite for accelerated ageing is that it should be comparable, qualitatively, to practice. The methods used hitherto for chemical ageing—the glycine test and acid-alkali test—do not meet this stipulation[12]. Leaching rate determinations cannot give more than a superficial indication of the anti-fouling properties of a composition at the moment of determination[6,13]. Any biological test should also be comparable to conditions in practice.

The results from two types of experiments carried out at the T.N.O. Laboratories indicate the necessity of amending the foregoing theory. The first series of results were obtained with a rotor apparatus for the accelerated ageing of anti-fouling compositions[6,14] used in conjunction with methods for investigating quantitatively the progressive ageing of compositions. The rotor apparatus consists essentially of a cylinder on which test panels are fastened. The cylinder can be rotated at a peripheral speed of up to 40 knots. The second series of results were obtained in experiments in which arbitrary scales of rating for fouling organisms were not used. The method of assessment consisted of measuring and counting accurately the numbers of organisms per unit area. This method could be used with ease in raft tests. For ship tests, separate panels were fastened on to bilge keels; this method has the advantages that in addition to being available for examination in the laboratory, the panels can be prepared under carefully controlled conditions and can be collected, if necessary by a diver during the voyage.

When using the rotor apparatus for the ageing of compositions, it was shown that they are affected in the same way as in practice but at an accelerated rate[6,14]. Compositions of moderate quality very soon—after one day—showed defects such as cold flow, inter-coat flaking or flaking of the wh[illegible] paint system from the substrate.

Quantitativ[illegible]on on the release of copper from the [illegible]ns was obtained in two ways [illegible]paratus and on ships: by [illegible]t of copper before and [illegible] examination of cross- [illegible] copper in the film [illegible]ht and formula-

of the tests demonstrated that the erosion, if any, of a composition by water flow was very limited even when the water speed was as high as 40 knots[6,29]. Also, that the difference between the release of poisons from soluble- and insoluble-matrix types of compositions were not so pronounced as was previously thought[17].

In both types of compositions, copper was liberated in the sea-water mainly by diffusion through the matrix. Further, it was shown that the differences in the lives of the two types of compositions could be explained by the formation of a copper-containing surface deposit in the exhausted matrix of an insoluble-matrix composition. The surface deposit was not detected in the soluble-matrix compositions. The bluish-green deposit which forms on many anti-fouling compositions after ageing may consist of a very insoluble product from the reaction of the paint-ingredients and sea-water; its exact composition is still unknown, although many authors consider it to be basic copper carbonate. It was not possible, however, to detect any carbonate group in the surface deposit when using attenuated total reflexion. The surface deposit is considered to have a very favourable effect on the life of an anti-fouling composition because of its regulating effect on the release of copper from the film.

Studies were also made of the relationship between the composition of the paint film and the release of copper[6,14,30]. It appeared that a better understanding of this relationship could be obtained by introducing the concept of 'total soluble'—the total amount of all sea-water soluble or otherwise sea-water-sensitive materials in the dry paint, expressed as a percentage of the volume of the dry film. The closer the percentage of 'total soluble' approached the volume of a continuous contact structure, the better was the release of poison from the interior of the film. The concept of 'total soluble' is very useful in formulating anti-fouling compositions based on copper or other poisons. For a full understanding of these phenomena, additional investigations into the solubilities of the ingredients in sea-water are necessary.

Wisely[15] considers there are three distinct mechanisms by which an anti-fouling composition can prevent fouling: (*a*) the fouling larvae are repelled and move away; (*b*) the fouling larvae become moribund before attachment and leave no trace on the paint (pre-attachment mortality); (*c*) the fouling larvae attach themselves to the paint and die during or shortly after metamorphosis (post-attachment mortality).

Wisely[16–18] has given examples of organisms which are repelled or which show pre-attachment mortality, while post-attachment mortality has been described by Crisp and Austin[19] for *Balanus balanoides* (L.) and *Elminius modestus* Darwin, and by De Wolf[20] for *Balanus crenatus* Bruguière and *Balanus amphitrite* Broch. These three observations only differ as a result of the differences in the rate of loss of copper from an ageing anti-fouling composition; in the case of *Balanus crenatus*, for example, a very high rate of release of copper acts either as a repellent or by means of pre-attachment mortality, while at lower rates of release, post-attachment mortality prevails.

Many authors state that, as a result of their experimental work, cuprous oxide anti-fouling compositions will prevent fouling so long as copper leaches from the film at a rate greater than 10 μg/cm²/day (refs. 1, 3 and 15). This statement is open to criticism, however, since the leaching rate is determined under well-defined conditions of temperature, flow, aeration, salinity and surface-to-volume ratio. On the other hand, fouling occurs under conditions which may differ considerably from the conditions of the leaching rate determinations in the laboratory. A leaching rate of 10 μg/cm²/day can only be used as an indication of conditions for the prevention of fouling[20].

Results published previously[6] have shown that a value of 10 μg/cm²/day is not always a reliable guide. Table 1 demonstrates that even at very low leaching rates, a considerable proportion of compositions do not foul.

An explanation of these phenomena has been proposed by De Wolf[20] using the assumption that the release of copper from an anti-fouling composition during leaching rate determinations or in raft tests is not homogeneous over the surface of the test panel. Indications that this assumption is correct are to be found by the examination of cross-sections of films. In an aged anti-fouling composition the layer of residual cuprous oxide shows considerable variations in thickness; the thickness of the layers is not constant if the film is applied by brush. This effect will be exaggerated still further if the composition is applied by roller on a relatively rough surface such as a ship's hull. This could explain, at least in part, why an anti-fouling composition on a ship's hull is always superior in performance when applied on a specially prepared patch of relatively small size compared with its performance over a whole ship. Results obtained by the accurate counting of barnacles on aged anti-fouling test panels and controls also support this assumption.

Over-dispersion of various species of young metamorphosed barnacles on non-toxic surfaces has been noted by several authors[22–24], and Wisely[25] has described the same effect of spacing-out of individuals from each other for the polychaetous worm *Spirorbis borealis* Daudin. In all these cases the dispersion of the animals is significantly more even than a dispersion according to a Poisson distribution with the same mean value.

Adult barnacles on a relatively smooth non-toxic surface may also be overdispersed; it has been observed that dispersion of adult barnacles on smooth aged anti-fouling compositions is nearly always significantly more uneven than a dispersion according to the corresponding Poisson distribution. This was found for *Balanus amphitrite* on bilge keel panels and for *Balanus crenatus* on raft panels. This under-dispersion cannot be explained by an inter-individual variation in sensitivity to copper since this would require the assumption that, during the process of settlement, a barnacle cyprid would be influenced by its neighbour's sensitivity to copper.

A variation in the release of copper over the surface, on the other hand, can easily explain the occurrence of under-dispersion in the barnacle population. The assumption in this case is that post-attachment mortality of barnacles will be most pronounced at places where the release of poison is highest. The barnacles present will then serve as indicators for locating where the release of copper is lowest—a kind of biological chromatography. The result would be that the final distribution of barnacles would be governed both by the original distribution of the settled larvae and the distribution of the poison over the surface of the aged composition.

It has been shown that barnacle cypris larvae are very insensitive to copper[26–28], and post-attachment mortality of barnacles is possible by contact poisoning; the copper diffuses directly from the anti-fouling composition into the metamorphosing barnacles[20], and not via the sea-water. This fact is in good agreement with the hypothesis formulated here since poisoning by direct contact stresses the importance of distribution of poison.

Table 1. Relation Between Leaching Rate of Paints and Fouling with *Balanus crenatus* in Raft Tests

Leaching rate of copper in μg/cm²/day	Total No. of panels exposed	No. of panels fouled	No. of panels not fouled
<1	16	11	5
1	17	7	0
2	6	4	2
3	11	8	3
4	6	6	0
5	3	1	2
6	8	3	5
7	3	1	2
8	5	0	5
9	6	4	2
10	4	3	1
11	2	1	1
>12	22	0	22
non-toxic controls	41	41	0

The work referred to in this report forms part of a programme on the fouling and corrosion of the hulls of ships, executed by the Paint Research Institute T.N.O. and the Central Laboratory T.N.O. (Biology Department) in collaboration with the Netherlands Research Centre T.N.O. for Shipbuilding and Navigation. The work is being sponsored by a number of composition manufacturers, the shipowners and the shipyards in The Netherlands.

MEASURING THE DENSITY AND DIRECTION OF MOLECULAR FLOW IN HIGH VACUUM USING AN IONIZATION GAUGE

By L. HOLLAND and C. PRIESTLAND

Central Research Laboratory, Edwards High Vacuum International Ltd., Crawley, Sussex

THE unit of pressure, that is force per unit area, is widely used to express the state of the residual gas in a high vacuum system. However, the most commonly used vacuum instruments are ionization devices which respond to gas density and are 'pressure' calibrated at a given temperature. Vacuum workers are concerned with kinetic systems in which gas is continuously evolved and removed from an envelope and the density must vary with position (even when the gas temperature is uniform) and the true pressure at any place will depend on direction. A single 'pressure' reading is usually insufficient to express the true state of the gas in a vacuum vessel, particularly if gas is evolved from a localized source. The important characteristics of a high vacuum for most uses are the gas composition, molecular mean free path and surface impingement rate. To determine the latter for a known gas one must measure its density, preferred flow, if any, and temperature.

There has been a tendency to treat the gas in a kinetic vacuum system as if it were static for measurement purposes and therefore vacuum workers have generally ignored the effect of gas beams on the response of their gauges. We have recently been measuring gas density and flow within a vacuum vessel using a Bayard–Alpert (B.A.) ionization gauge, and the effect of the gauge tubulation and orientation on its response is discussed here.

Gas molecules with a density n in an element of volume may be composed of a number n_c with a chaotic distribution and a balance n_s with a preferred direction of flow. If an ionization gauge is exposed to both components then a total ion current will be indicated given by $I = I_c + I_s$. If the gauge has been calibrated in terms of pressure then one reads a total pressure $P = P_c + P_s^*$, where P_s^* is a hypothetical quantity equal to that a molecular beam of density n_s would have if its preferred direction was replaced by chaos.

Should a gas beam impinge on a plane, then the true pressure P_B due to the beam is a function of direction and composed of two components. The impact of the beam at normal incidence produces a pressure $n_s m v_R^2$, where m is the mass of the gas molecules and v_R their root mean square velocity. As the re-emitted molecules leave in random directions their reaction thrust on a receiver at the gas temperature is $n_s m v_R{}^2 2/3$. Therefore, $P_B = n_s m v_R{}^2 5/3$, and as $P_s^* = n_s m v_R{}^2/3$ we obtain $5P_s^* = P_B$.

When an ionization gauge is used to measure beam density its response will depend on the shape and conductance of its tubulation. If the gauge envelope has a small opening in a thin plate of area A normal to a parallel molecular beam then gas will stream directly into the head, but to leave, it must find the opening by a random process. Thus, the gas density n_e of the beam within the enclosure is given by the equilibrium equation $An_s\bar{v}_s = An_e\bar{v}_e/4$, where $\bar{v}_s$ and $\bar{v}_e$ are the average molecular velocities; when the temperature is constant $P_e = 4\ P_s^*$. This effect was used by Stern[1] to enhance the detection of a molecular beam by a pressure manometer. Later, Frisch and Stern[2] used a canal to obtain a higher pressure factor.

Huntoon and Ellett[3] have used an ionization gauge for detecting weak mercury-beams with a long canal aperture. However, in general vacuum work the gauge tube must usually have a full bore opening to avoid sorption within the head affecting the pressure reading, and it is necessary to determine the enhancement factor of such a head before it can be used to measure beam density. Molecular flow arising from localized desorption in high

vacuum systems may occur in any direction over a large solid angle. Thus the beam detector must be capable of translation and rotation.

The high vacuum system used by us had a vessel (19 in. diam., 24 in. high) made of stainless steel exhausted by a diffusion pump, charged with silicone *DC*.704 and fitted with a water-cooled baffle valve. The baseplate pumping aperture was 12 in. diam. and the horizontal valve plate 9·5 in. diam. The baffled pump speed was 690 l./sec. A circular plate was inserted in the vessel to divide it into two compartments and the air pressure in the upper compartment controlled by a needle valve. The lower compartment had a height which was about equal to its diameter (as shown in Fig. 1). Pressures were measured by a Penning gauge P_1 in the high-pressure compartment and a B.A. gauge P_2 in the low-pressure compartment; both gauges were calibrated against a McLeod gauge. The beam detector was mounted in the lower compartment with its filament electrodes always normal to its plane of movement to preserve symmetry when varying the incidence angle.

The B.A. electrodes of the beam detector were mounted in a stainless-steel tube of $1\frac{5}{8}$ in. diam. by $2\frac{1}{4}$ in. length, as shown in Fig. 1. The grid was $\frac{3}{4}$ in. diam. and because ion collection was limited to ions formed within this region the resolution of transverse density variation was determined by the grid rather than the tube diameter. The sensitivity of the beam detector in terms of ion to electron current ratio was 15/torr and equal to that of the ion gauge P_2 which had the same electrode arrangement. The amplifier used with the beam detector had a backing-off facility allowing the measurement of ion currents of about 10^{-10} amp on a background level of 10^{-8} amp; values of $P_g^* = 10^{-7}$ torr could be measured in the presence of $P_c = 10^{-5}$ torr.

Initial measurements were made of the density at different incidence angles produced by gas effusing from the high-pressure vessel through an aperture (2·26 cm diam.) in a thin plate. The beam intensity for free molecular flow at a distance l from the source is given by $n_s\bar{v} = N \cos\theta \cos\varphi/\pi l^2$, where N is rate of molecular effusion and θ and φ are the angles of incidence at the emitter and receiver planes, respectively. $N = A\, n_1\, \bar{v}/4$, where n_1 is the density of gas in the upper vessel and A is the aperture area.

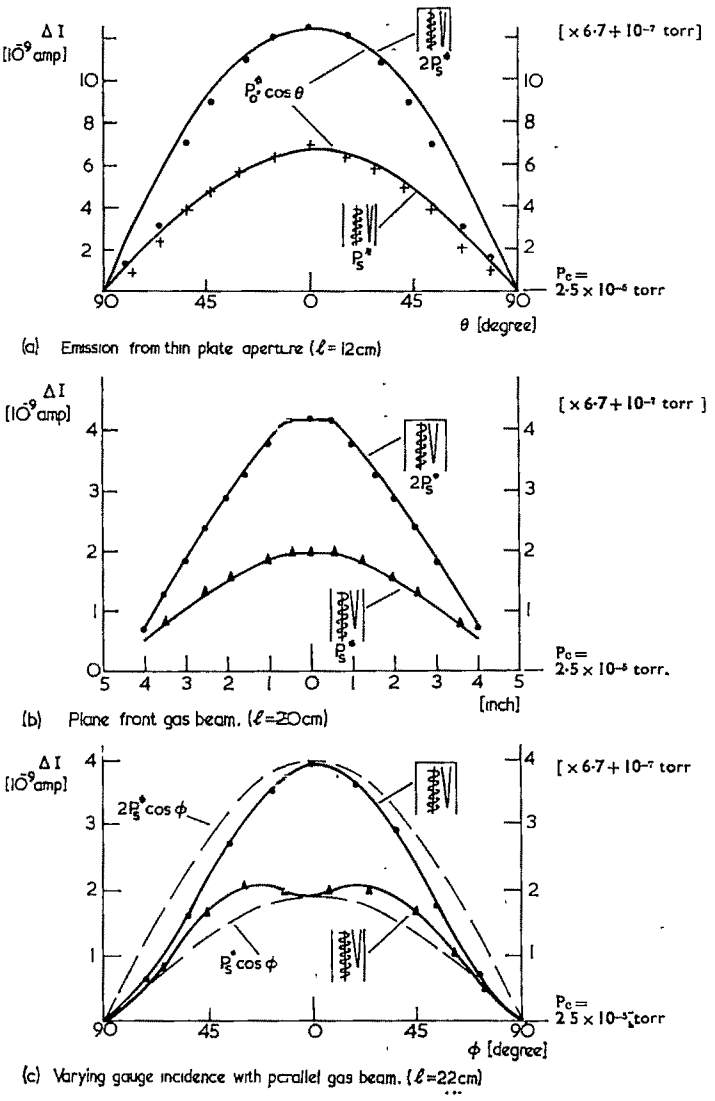

Fig. 2

With $P_1 = 10^{-3}$ torr, $P_2 = 5 \times 10^{-5}$ torr, and the beam detector at $\theta_u = 90°$, the beam current could be set at zero as cos 90° = 0. When the detector was turned around the gas source the expected cosine dependence of ion current on incidence angle was obtained (Fig. 2*a*). Using the same beam conditions the tubular detector was closed at one end to deflect the streaming gas back into the head and this doubled the ion current as shown in Fig. 2*a*. The gas molecules beaming into the detector at $\varphi = 0$ are scattered by collision with the end-cover and pass, on average, once more through the ionizing region. P_c did not vary with the detector position because of the apparatus design. P_c was equal to the equilibrium pressure P_2 given by the relation $Q = P_2 S$, where Q was the quantity of gas entering the system in unit time and S its volumetric rate of removal.

Having established that the beam detector gave an ion current proportional to n_s for $\varphi = 0$, experiments were made at a constant beam density and varying detector incidence. To provide a

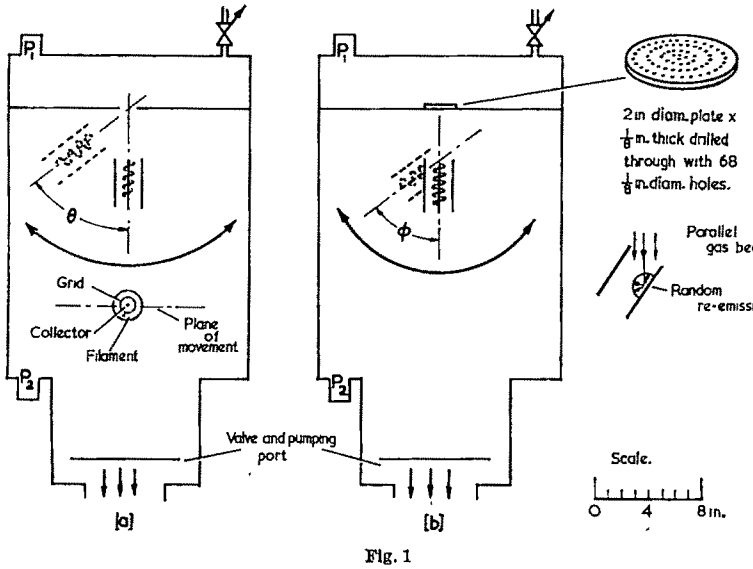

Fig. 1

parallel beam of uniform intensity a plate $\frac{1}{8}$ in. thick by 2 in. diam. was drilled with 68 holes $\frac{1}{8}$ in. diam. so that the individual gas streams formed a single uniform base. The ionization detector was initially traversed at normal incidence across the molecular beam with l constant and this showed a central region of uniform beam density of 1·5 in. diam. comparable with the diameter of the detector tube.

The detector was then rotated in the uniform beam region to vary φ with l constant. The results plotted in Fig. 2c show that the closed gauge gave readings only approximating to a cosine function of φ. When the detector end-cover was removed the sensitivity in terms of beam density decreased as expected, but the I_s versus φ curve had a maximum either side of $\varphi = 0$. When the beam was incident normally the stream passed directly through the open tube, but for $\varphi > 0$ the molecular beam struck the tube wall and was re-emitted into the ionizing region. When the detector was turned on its cylindrical axis to bring the filament into the plane of incidence the I_s versus φ curve became asymmetric.

It follows from the foregoing that a B.A. gauge with a tubular envelope of high conductance can be used to find the components of gas density with a random distribution and preferred direction, that is, n_c, n_s and φ, respectively. However, it is first necessary to determine the beam enhancement factor as a function of the inlet incidence φ angle for the particular gauge used. The instrument cannot show whether a direction of greatest density flow arises from a single beam or a combination of beams with different directions, because it does not measure molecular velocity in any direction. However, the device may find use in systems exhausted at high pumping speeds, for example, by a cryopump, or in apparatus used for measuring the speed of pumps or calibrating vacuum gauges.

A SYSTEM OF MESOPIC PHOTOMETRY

By Dr. D. A. PALMER
National Physical Laboratory, Teddington, Middlesex

To the dark-adapted or scotopic eye, lights of different spectral power distributions, say $E_1(\nu)$ and $E_2(\nu)$ per unit wavenumber interval, will have the same luminosity if:

$$\int E_1(\nu)\, V'(\nu)d\nu = \int E_2(\nu)V'(\nu)d\nu$$

where ν is the wavenumber of monochromatic radiation, and $V'(\nu)$ is the scotopic luminosity function, such as that defined by the Commission Internationale de l'Éclairage (C.I.E.) for the 'standard eye'. A similar equation holds for matches with the light-adapted, or photopic eye, except that $V'(\nu)$ is replaced by $V(\nu)$, the appropriate C.I.E. function for this condition. V and V' are analogous to the response functions of photoelectric cells, and may be defined as the reciprocal of the power of monochromatic radiation of wavenumber ν, required to produce a certain degree of visual sensation under the appropriate conditions. The scale is usually such that V or $V' = 1$ at the wavenumber for which the function is greatest[1]. However, in what follows, the functions will be normalized so that their integrals will give a direct measure of the equivalent luminance of the test source when compared with the standard full radiator source at 2,042° K. That is, two integrals may be defined:

$$S = \int E(\nu)\, v'(\nu)d\nu$$
$$P = \int E(\nu)\, v(\nu)d\nu$$

where S is called the 'scotopic equivalent luminance', P the 'photopic equivalent luminance' of the source, and $v'(\nu)$ and $v(\nu)$ are the normalized scotopic and photopic functions.

Now in general, because of the difference in shape between v' and v, a light of spectral power distribution other than that of the standard white itself may not have the same values for S and P. For example, a red light, originally matching the standard at a low level, may look some hundred times brighter than the standard when both lights are increased in the same physical proportions so as to be in the photopic condition. This is an example of the Purkinje effect[1]. The problem is to predict the photometric relation between lights in the mesopic range, that is, between true scotopic and true photopic conditions.

Solutions to this problem have been bedevilled by the notion that there ought to be a series of functions appropriate to the mesopic eye, intermediate in shape between v' and v, and of the same integrating properties. That this applies approximately in some cases at least has been reported by the C.I.E. committee on mesopic vision[2], but in general the method is not satisfactory (see, for example, the comments of Bridgman[3] and Wright[4]). Even if this approach works perfectly, the appropriate function cannot be precisely known until after measurement of the light source, and must therefore be found by a tedious iterative method of successive approximations.

Another approach which seems to work within an observer's experimental precision may be illustrated by

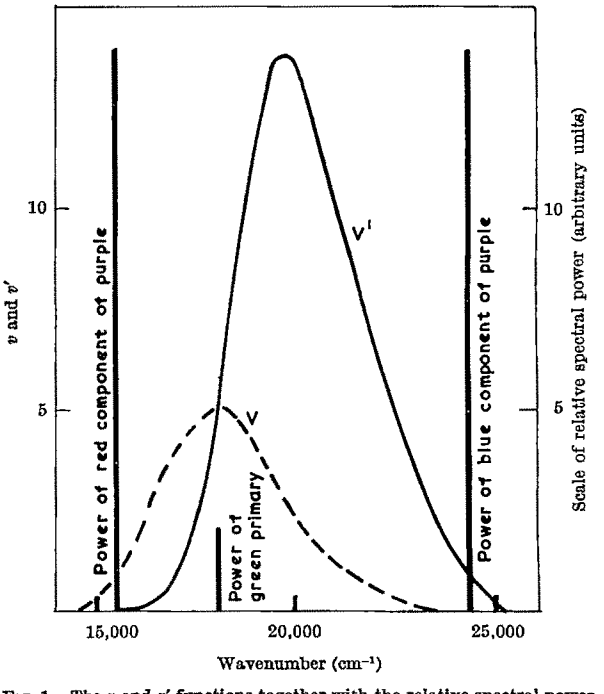

Fig. 1. The v and v' functions together with the relative spectral power distributions of a green and a purple test light of the same scotopic and photopic luminances, to illustrate the proposed method of mesopic photometry

Fig. 1, which represents the v' and v functions. Consider a monochromatic green light taken at the wavenumber where the curves intersect. Obviously the light has the same scotopic and photopic luminances S and P. That is, $S = P = L$, where L is the luminance of the matching standard. Consider also the purple light composed of two monochromatic radiations, a red at a wavenumber where v is much greater than v', and a blue at a wavelength where v' is much greater than v. Obviously the components may be adjusted to give this purple the same values for S and P as the green light, the blue component contributing most of the scotopic luminance and the red most of the photopic luminance. Thus these purple and green lights, together with the white standard illuminant itself, if adjusted to match each other at scotopic levels, will also match at photopic levels when they are all increased physically in the same proportion. It seems not unlikely that they might also keep in match in the mesopic range, approximately at least. If this were so, then by extension the same property would probably be found in a huge family of purples, greens and whites of various spectral types, monochromatic and continuous, all characterized by $S = P$. The next obvious generalization is that the photometric behaviour of lights in the mesopic range could possibly be characterized by their pairs of integrals S and P (or by other pairs of functions derived from these) where, unlike the above examples, S has not necessarily the same value as P. Experiments were therefore made to test this hypothesis.

An immediate difficulty in the design of the experiments was that the C.I.E. V' function is defined for a 20° field eccentrically fixated as in Crawford's[5] original work, while the V function is defined for a 2° field centrally viewed. Hence, an experimenter wishing to bridge these conditions must decide how to change his method of viewing systematically through the mesopic range. Fortunately, the C.I.E. has recently suggested a photopic function for a 10° field centrally viewed[2], so it was decided to use a similar field throughout, in the hope that the V' function would not be totally inappropriate to this condition. This choice was underlined by the use of the National Physical Laboratory's trichromator[6,7] on which, indeed, Stiles had measured the new 10° photopic function.

The next problem was the choice of conditions for heterochromatic photometry. As is well known, heterochromatic matching by direct comparison is not particularly additive at photopic levels[4], and additivity, or something like it, is desirable in all photometry. On the other hand, flicker photometry, although additive at photopic levels, is not satisfactory in the mesopic range[4] because the flicker is then difficult to see. Therefore to compare these conditions it was decided that one observer (D. A. P.) should make both flicker and direct comparison matches at several levels (see later).

The central tier of the trichromator was used to provide thirty different test lights, which included fourteen monochromatic radiations of the purity reported by Stiles[6,7], and eight combinations of two or more of these. The remaining eight test lights had continuous spectral distributions and were obtained by removing the central slit and mask and inserting coloured filters. Since the trichromator is an excellent double monochromator, the relative spectral power distributions of the test lights could be measured by running a slit through the spectrum, while recording the output on a photomultiplier whose spectral response had been measured in the Radiometry Section of the National Physical Laboratory.

The relative spectral power distributions per unit wavenumber interval of the test colours together with the numerals used in the diagrams are given in Table 1 (the colour names are intended only as rough guides to the appearance of the lights). It was convenient to express the radiation in wavenumbers because Stiles had already

Table 1. Spectral Specifications of the Test Lights

The fourth digit in each value is an index representing the multiplying power of 10. Where appropriate, the values are normalized to 100 (1·00 + 2) at 15,500 cm^{-1}

used the instrument in this way[6,7]. Some of the chosen wavenumbers are Stiles's primaries, the rest are interpolated to give fourteen evenly spaced points through the visible spectrum. Included among the lights is a white (light no. 30) corresponding as closely as possible to a full radiator at 2,042° K. This is the standard source recommended by the C.I.E. for photometry[2], so that physical measurements of its power may be taken as a direct measure of its luminance. In fact, the actual source had an equivalent colour temperature of about 2,060° K, and its chromaticity ($x = 0{\cdot}520$, $y = 0{\cdot}417$, $z = 0{\cdot}063$ in the C.I.E. 2° system) fell on the green side of the locus, the red and blue regions of the spectrum being slightly deficient. This slight variation from the ideal standard does not invalidate the principle of the method described here, and a correction can be applied to relate the data to the ideal radiator (see later).

The luminance L of the standard field was measured at several levels with a Macbeth illuminometer previously calibrated against a standard lamp at 2,042° K. The corresponding outputs from the photomultiplier were measured to establish a scale for L. The photocell and associated equipment had been found to be linear to within ±2 per cent over the large range used. In the data, the field brightness will be expressed in trolands entering the eye from the aerial pupil, the dimensions of which were about 1·0 mm horizontally by 1·5 mm vertically.

The standard and other test lights could be attenuated neutrally over the enormous range required by means of gauze screens and an iris, through which the light from the lamp fell on to a translucent diffusing screen in front of the entrance slit of the instrument. Some stray light at low levels, no great problem in a good double monochromator, was removed with baffles.

The field was circular, 10° in subtense, with a dark surround. It was divided horizontally for the direct comparison matches, the test lights, including the standard white, appearing in the upper half of the field. They were matched in turn against another white light in the lower half, of nearly the same chromaticity as the standard, but the spectral distribution of which was not so closely known. However, this knowledge was not strictly necessary, as the lower white field served merely as an intermediary for the comparison of the test colours with the standard white. By this substitution technique, the test colours were in fact compared with a standard which occupied the same part of the visual field as themselves. For flicker photometry a similar substitution method was used except that the test lights and the intermediary white now occupied the whole field successively. After each match had been made, the observer removed his head from the dental impression and forehead rest, to permit measurements of the amounts of light on both sides of the match with the calibrated photomultiplier in the manner described by Crawford[8].

From these measurements and from the photomultiplier response, the spectral power distributions being known, it was possible to calculate the values of the integrals S and P for each light in match with the standard of luminance, L. The C.I.E. scotopic function was used to compute S, and the proposed C.I.E. 10° photopic function was used to compute P.

The observers made matches at levels selected from the following: (1) 620 trolands; (2) 62 trolands; (3) 6·2 trolands; (4) 0·62 trolands; (5) 0·062 trolands; (6) 0·0062 trolands; (7) 0·00062 trolands. At the lowest level, which is only some three times greater than the visual threshold, and at levels 5 and 6, the observers were dark-adapted for 1 h before making matches. At level 4, half an hour's dark adaptation was deemed sufficient, and for the other levels there was no adaptation from the normal room illumination. Even at the lowest levels, the deep monochromatic reds, below 16,375 cm^{-1}, still retained their reddish appearance. Only a selection of the test lights was used at the highest and lowest levels, which were done merely to ensure that true photopic and scotopic conditions had been reached. Miss B. J. W. used only a selection throughout.

The observers' ages were; Miss B. J. W., twenty-one years; J. F. C., twenty-three years; D. A. P., thirty years.

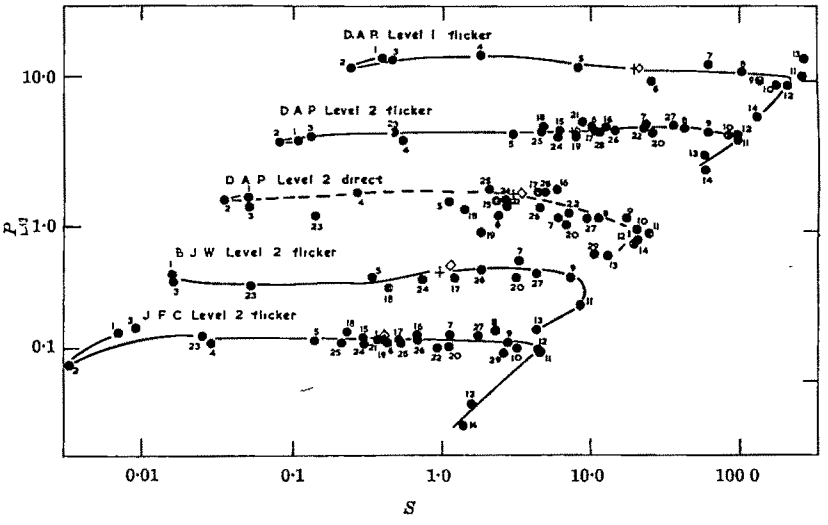

Fig. 2. Logarithmic plots of the photopic luminance, P, against the scotopic luminance, S, for each test light matching the standard at level 1, 620 trolands, and at level 2, 62 trolands

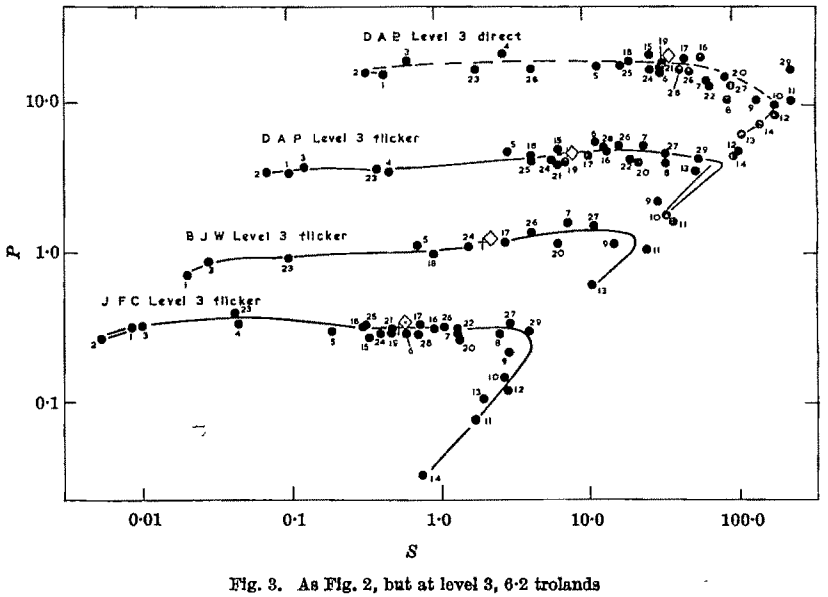

Fig. 3. As Fig. 2, but at level 3, 6·2 trolands

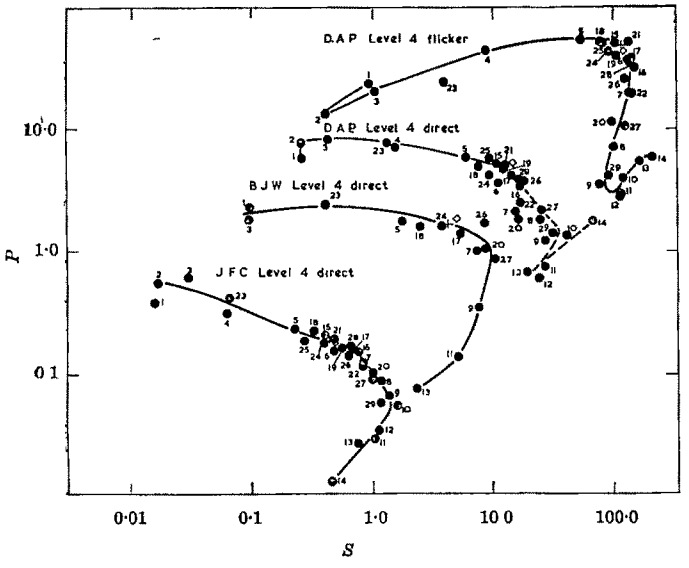

Fig. 4. As Fig. 2, but at level 4, 0·62 trolands

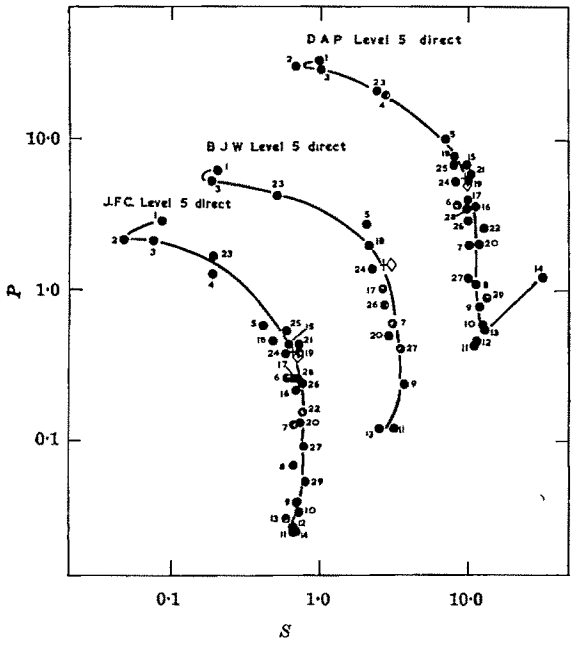

Fig. 5. As Fig. 2, but at level 5, 0·062 trolands

The observers allowed their eyes to roam freely, but made their final matches while looking towards the centre of the field, judging it as a whole. They were not troubled by any apparent non-uniformity in the field. Fifteen to twenty matches were made for the important comparisons between the standard white and the intermediary, and three to five matches for the other test lights. The arithmetical average of each set was used to plot the diagrams.

A convenient and descriptive way of displaying the results is to plot log P against log S for the set of test lights matching the standard at a given luminance, L. If the hypothesis holds, then lights matching the standard and having the same ratio between S and P should all fall together in the diagram at the same point. In other words, the locus of log P against log S for a given value of L should be unique.

The experimentally determined points are shown in Figs. 2–6. The luminance-level and conditions of match, whether by flicker or direct comparison, are given in the diagrams. The curves have been shifted along the 1 in 1 line by an arbitrary amount in order to display each observer's results separately. This may be done with a logarithmic scale, of course, without distorting the shape of the graphs. The point where $S = P = L$, representing the luminance of the standard white at which each curve was obtained, is shown as a lozenge (◈).

If the hypothesis holds, the loci should pass through this point, as indeed they generally do. The loci are very distinct with no great spread of points about themselves. The exceptions, the direct comparison results (D. A. P.) at the highest levels, apparently display non-additivity. The more saturated the colour, the less is required for a match against the standard white than would be expected from the computations from the $v(\nu)$ curve (the Helmholtz–Kohlrausch effect).

In general, however, the standard deviations of all the points about the mean loci, averaged for the three observers, are ± 7·6 per cent at level 2 (flicker, photopic), ± 7·1 per cent at level 3 (flicker, mesopic), ± 8·8 per cent at level 4 (direct comparison, mesopic), ± 6·6 per cent at level 5 (direct comparison, mesopic), ± 8·5 per cent at level 6 (direct comparison, scotopic). These figures illustrate that the precision of this method in specifying luminances in the mesopic range is comparable with what is found in photopic (flicker) and scotopic (direct comparison) photometry. Indeed, the deviations must largely reflect the precision of the observer since there is no systematic tendency to set particular matches above or below the mean locus, with the exceptions just noted.

On the other hand, if 'mesopic luminosity functions' are derived from the monochromatic matches, and used to predict the matches for the test lights of more than one

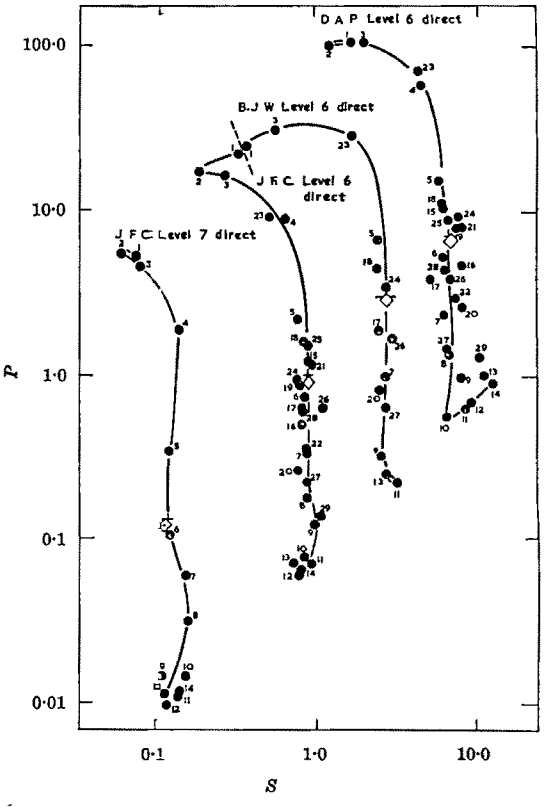

Fig. 6. As Fig. 2, but at level 6, 0·0062 trolands, and at level 7, 0·00062 trolands

primary, then the standard deviations of the errors become much larger, for example, some ±20 per cent at level 4. The purples fare particularly badly with this method. For example, from J. F. C.'s results at level 4, the discrepancies are −15 per cent for light No. 19, +27 per cent for No. 20, +22 per cent for No. 21, +29 per cent for No. 22, −28 per cent for No. 24, compared with discrepancies of 0, +3, +6, −2 and −4 per cent for the same matches plotted on the S, P diagram.

The expected shape of the loci will now be discussed. For an 'additive' eye, scotopic conditions should produce a series of rectilinear loci parallel to the log P axis, and similarly, photopic conditions should produce rectilinear loci parallel to the log S axis. Approximations to such loci are found, but there are important deviations from the ideal scheme. The scotopic curves, for example, are still curled at the red end, even at the lowest level (see, for example, J. F. C.'s level 7), which is lower than that at which Crawford[5] determined the scotopic function. The effect is almost certainly due to the observers' viewing the field centrally, thus using more cones than did Crawford's observers. However, the loci are well defined in the red end (for example, the deep red test light No. 23 with a continuous spectral distribution fits well with its neighbouring monochromatic lights), and in any event it is fruitless to search for a series of parallel lines in the reds at scotopic levels, as the deep reds, notoriously, never appear to settle down to true scotopic conditions[4]. Another peculiarity is the tail on each locus at the violet end, which means that the photopic function is too low there by a factor of two or more. Probably since the present observers are younger than the mean age of Stiles's[6] observers (to whom the photopic function is due) they have not yet acquired so much yellow pigment in their ocular tissues, and hence are more sensitive to violet light. If the photopic function were adjusted to eliminate the tails, the loci would still double back on themselves (similar loops are found at the red end). These are because the v' function at first falls less quickly than v, but then starts to catch up, with the roles of the functions reversed at the red end. The loops are found on most loci, whether photopic, mesopic or scotopic, but as they affect only the extremities of the spectrum they are probably not very important practically.

In short, the C.I.E. scotopic function and the proposed 10° photopic function serve well for the computation of S and P for the three observers, with the reservations just noted. The agreement between direct comparison and flicker photometry is not perfect, especially at the ends of the spectrum (for example, D. A. P.'s results in Fig. 4), but for most test lights the discrepancies are not great.

In the mesopic range the shape of the loci can be found only by experiment. The main point of the experiments is that mesopic loci can indeed be determined, as definite as those for photopic and scotopic conditions. A system of mesopic photometry based on the S, P diagram is therefore possible.

In this connexion, the most interesting families of lights are the greens, purples and whites which lie so close to each other in the diagram, showing that colours of different chromaticities may behave similarly in photometry, provided that their S, P co-ordinates are similar.

The reds, oranges and yellows also show this, together with the complementary phenomenon that colours of the same chromaticity need not lie near to each other in the S, P diagram. For example, the yellow light No. 25 falls some distance from the monochromatic yellow No. 5 of similar chromaticity, while No. 18, of almost the same chromaticity as the red No. 23, falls closer to the yellow No. 25.

These observations illustrate that the integrals $S = \int v'(\nu)\, E(\nu)d\nu$ and $P = \int v(\nu)\, E(\nu)d\nu$ are not the same as their mathematical analogues in colorimetry:

$$X = \int \bar{x}(\nu)\, E(\nu)d\nu;\quad Y = \int \bar{y}(\nu)\, E(\nu)d\nu;\quad Z = \int \bar{z}(\nu)\, E(\nu)d\nu$$

although of course $v(\nu) = \bar{y}(\nu)$ in some systems. These resemblances and differences between S, P and X, Y, Z were pointed out by Mr. J. N. Greene.

To sum up, the experiments suggest a simple and accurate system of mesopic photometry, which corresponds to what observers actually see, and which takes in the scotopic and photopic conditions as special cases. As an example of the system in practice, only two photocells would be required, corrected to appropriate scotopic and photopic luminosity functions. The equivalent luminance of any source could then be measured by comparing responses on the cells with those for the standard light-source at 2,042° K. These measurements would yield S and P, which would then be plotted as a point on an S, P diagram with loci determined for the 'average' observer. The equivalent luminance L of the unknown source would then be read off directly by interpolation between the loci of constant L, whether L lay in the scotopic, mesopic or photopic ranges.

As mentioned earlier, it may not be necessary to have a perfectly ideal source at 2,042° K in order to make the measurements for the 'standard observer'. Provided that he obeys the laws apparently in evidence here, it would be permissible to use the results to compute the luminance of the ideal radiator when compared with the standard actually used, and from this computation, to refer all other sources to the ideal. This mathematical process is like a transformation to ideal primaries in colorimetry. The points representing the ideal source computed from the present data are shown as crosses (+) in the S, P diagrams.

A better theoretical argument than the heuristic approach sketched out in the introduction will now be attempted. The sufficiency of only three integrals to define chromaticity has always been taken as strong evidence for three types of retinal receptor mediating in the perception of colour. Thus the present requirement of only two integrals S and P to define equivalent luminance, which are mathematically similar to the chromaticity integrals, might by analogy imply the existence of only two types of receptor to mediate in the perception of luminosity, even if not more were known. But of course the scotopic and photopic functions are already assumed, from other evidence, to represent the activities of the rods and the cones—very plausible candidates for the role of luminance detectors. The integrals S and P could therefore be regarded as representing the basic responses of the rods and cones, which are combined by the eye in a proportion depending on the level, to give the perceived luminosity. At low levels the rods alone would contribute, and at high levels only the cones, with both types effective at mesopic levels in the proportions implied by the loci of constant luminance in the S, P diagram. It follows that lights stimulating the rods and the cones in the same ratio before the summation process is considered would exhibit identical photometric behaviour at all levels. From this point of view, the phantom mesopic luminosity functions vanish.

Of course the scheme is complicated by the existence of three types of cone, which presumably causes the discrepancies already noted in direct comparison matches at high levels. However, the present photopic results, measured by flicker photometry, agree well (except at the violet end) with Stiles's proposed 10° function derived from colorimetry which is, after all, another form of direct comparison matching. This suggests that an additive photopic luminosity function may be independent of the method of its measurement. Extensions of the present experiments could probably yield information about summation processes from pure cone and pure rod responses, but it is not intended to pursue this further here, but merely to demonstrate and to justify a practical method of mesopic photometry.

Of course, several questions remain unsettled. For example, is 10° the best field size? Can the difference

between flicker and direct comparison matching be bridged more satisfactorily? Is there sufficient agreement between normal observers to justify setting up a defined average? Should the measurements be done monocularly with a restricted artificial pupil, as in the present experiments, or should more natural binocular vision with unrestricted pupils be specified? The latter case involves, of course, the effect of pupillary contraction, and the great differences known to occur between observers in this respect. Do the scotopic and photopic luminosity functions need revision? It would be absurd, for example, to define a standard mesopic observer who was youthful scotopically and middle-aged photopically. It is hoped that further experiments will resolve these questions.

This work was undertaken as part of the official research programme of the National Physical Laboratory. I thank Mr. J. N. Greene for his help.

WIND DRAINAGE OFF THE HIGH PLATEAU OF EASTERN ANTARCTICA

By K. B. MATHER and G. S. MILLER
Geophysical Institute, University of Alaska, College, Alaska

It is well known that coastal stations on or close to the steep ice slopes of Antarctica experience strong downslope (katabatic) winds, the direction of which accords with the direction of maximum slope of the ice surface if allowance is made for the easterly component introduced by Coriolis acceleration. The mechanics of the air layer on a sloping surface under conditions of temperature inversion have been discussed by various authors, notably by Ball[1-3]. Quantitatively, the accelerations involved have the magnitudes $A_k \approx g\alpha\ \Delta T/T$ and $A_c = 2\Omega V \sin\varphi$, respectively, where g is acceleration due to gravity, α the surface slope, T the potential temperature, ΔT the inversion strength, Ω the Earth's angular velocity, V the wind speed and φ the latitude of the observing station. Superimposed on the katabatic component, in general, will be the acceleration due to the horizontal pressure gradient, $A_p = \Delta P/\rho$. The fact that most, if not all, coastal stations located at the foot of the steepest slopes record consistently downslope drainage during most of the year means that A_k is considerably greater than A_p. Moreover, it can readily be shown[3] that this result is quite plausible by making numerical estimates of A_k and A_p using reasonable values of ΔT and for the synoptic gradient.

However, coastal stations present a rather special case, with conditions weighted heavily in favour of the katabatic component because of the steep slope; α tends to average between 1 in 20 and 1 in 30 for the first 10 km inland, and may reach 1 in 10 within a kilometre or so of the shore. Further inland, the slope generally declines to 10^{-2} well within the first 100 km, although notable variations occur. (The most extensive fetch of steep slope is the hinterland of the Princess Astrid Coast, where α apparently averages about 10^{-2} for 400 km inland.) Across much of the central plateau of Eastern Antarctica α approaches 10^{-3}. For these much smaller values of slope, A_k can still be significant and possibly comparable with A_p, especially as severe inversions can be expected, but it has not been known whether the katabatic component is sufficient to manifest itself in the wind pattern in some recognizable form when cyclonic variations are superimposed. For instance, is there a general drainage off the high plateau to the coast and low-lying areas?

A previous attempt to answer this question[4-6] was based on an examination of wind data from around the vast depression in the plateau caused by the Lambert Glacier and Amery Ice Shelf. The argument ran as follows: the direction of maximum slope around the Lambert Glacier changes radically within a dimension of 500 km, which is small compared with the size of the continent. Whereas a 'prevailing anticyclone' over eastern Antarctica would tend to produce an anticlockwise circulation (not altogether inconsistent with what had been observed at a number of stations), it would be difficult to concoct a synoptic pattern that required winds to blow from the south at the south of the Lambert, from the west at the west of it, and from the east at the east of it, that is, a synoptic pattern which would match the expected gravity drainage. In fact, all available observations have confirmed that the Lambert Glacier is a 'sink' into which cold air drains from the surrounding plateau to the east, south and west, including slopes for which α was much less than 10^{-2}. The results established that the katabatic regime encompassed a much more substantial area of Antarctica than a narrow coastal strip.

Now, however, as a result of more numerous station and traverse-party observations during and since the IGY, there is much more evidence bearing on the katabatic question. The purpose of this article is mainly to present accumulated data on the gross drainage pattern, with emphasis on the high plateau of Eastern Antarctica, though not exclusively so. Data have been analysed from McMurdo, Hallett, d'Urville, Charcot, Wilkes, Mirny, Pionerskaya, Komsomolskaya, Vostok, Sovietskaya, Davis (and precincts), Mawson (and precincts), Syowa and the vicinity of Lutzow-Holm Bay, Norway Base, Maudheim, Molodezhnaya, Lazarev, Novolazarevskaya, Halley Bay, Shackleton, Ellsworth, South Ice, Amundsen-Scott, Little America, Byrd, Roi Baudouin, and from various traverse parties and a few ship's observations offshore. For the most part the data consist of surface meteorological observations, supplemented on the traverses by sastrugi directions, which are useful indications of prevailing winds[4].

Fig. 1 shows wind roses (frequency of occurrence of wind as a function of direction) in relation to plateau contours. The short arrows elsewhere on the chart represent traverse data obtained in passage; they are not long-term averages. Concerning the coastal stations, it is essential to know the exact siting of the observation point with respect to the foot of the ice slope. Some stations are on islands offshore, some are on ice shelves, others are on ice-free expanses of rock. As the katabatic wind peters out a few kilometres from the foot of the ice slope, such stations may not register the downslope drainage even though it is well developed on the ice slopes along that same stretch of coast. (By the same token, of

course, these stations are rather more useful for synoptic analyses.) Examples are McMurdo, Davis, Lazarev, Maudheim, Halley Bay, Shackleton and Little America, all of which can be disregarded in katabatic studies. Syowa, situated on East Ongul Island 4 km from the nearest ice slope, presents an interesting borderline case[7]. Hallett is also a special case because of its location near the tip of the long Hallett Peninsula, together with a complicated drainage zone due to the peaks of the Admiralty Range. Wilkes is about 3 km from the ice slope and the station is partly sheltered by low hills; the gravity drainage seems to be considerably impeded[8].

The broad conclusion from Fig. 1 is that the wind régime of most of Eastern Antarctic is consistent with an interpretation in terms of an appreciable katabatic contribution. With the exception of one station, nowhere are the most frequent station winds contrary to the downslope direction, modified for Coriolis deflexion. The best-documented portion of the inland is that from the Mirny-Wilkes coast to the Soviet stations on the plateau, and this affords another remarkable example, like that of the Lambert depression, in which gross changes in contour directions are matched by a complete reorientation of the prevailing wind. On the line from Komsomolskaya via Pionerskaya to Mirny, the drainage is downwards towards Mirny. The three stations Vostok, Komsomolskaya and Sovietskaya, all within 540 km of one another, are dispersed around the eastern end of the (approximately) 3,500-m contour of the high plateau in such a way that the direction of maximum surface slope changes by nearly 180°. As shown in Fig. 1, the wind swings correspondingly from approximately west at Vostok to south at Komsomolskaya and to east at Sovietskaya. The essentially opposite but collinear wind vectors at Vostok and Sovietskaya, on opposite sides of the ridge, have been noted also by Russian meteorologists[9], who interpreted the behaviour as due to katabatic flow. Even more interesting, perhaps, is the fact that Vostok and Sovietskaya are only 420 km apart, which would seem to imply that katabatic winds can develop in quite a short stretch of slope, that is, the flow at any point reflects only the very local conditions of slope and inversion. Notice also the shift in direction in the course of a very short distance from Komsomolskaya on the traverse to Sovietskaya.

Although there is still little information about the winds on the western part of the plateau, for example, between the South Pole and the Princess Astrid and Princess Ragnhild Coasts, it now seems fairly certain that wind drainage must occur outwards from all parts of Eastern Antarctica, even where the slopes are $\sim 10^{-3}$. This alone does not prove that the flow is due to gravity but the pattern is strongly suggestive of a gravity contribution in many areas.

Some examples of inland slopes are: Pionerskaya $2{\cdot}9 \times 10^{-3}$, Komsomolskaya $1{\cdot}7 \times 10^{-3}$, Sovietskaya and Vostok about $1{\cdot}5 \times 10^{-3}$. These figures are all

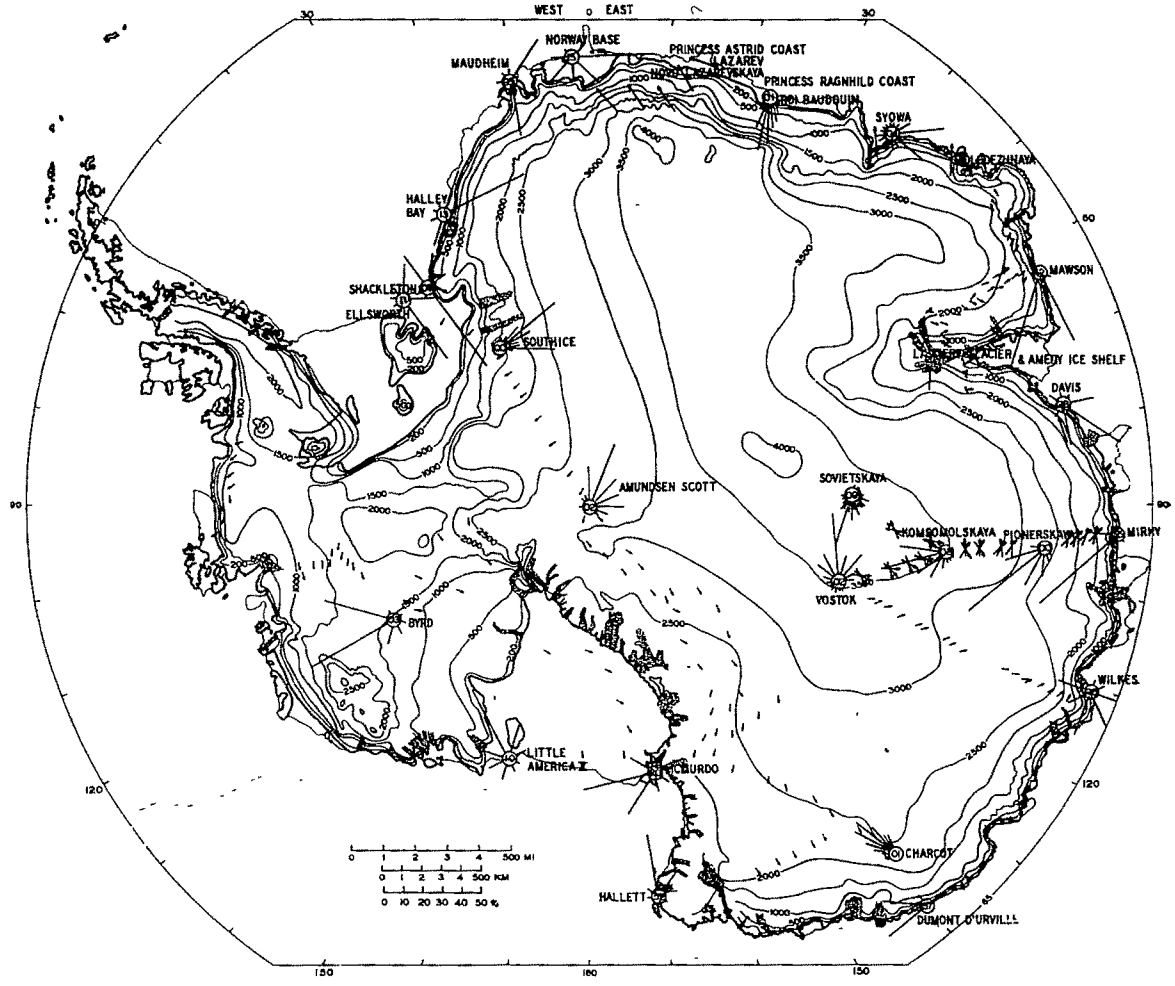

Fig. 1. Wind roses and sastrugi orientation. The orientation of snow dunes has been included on some traverses, for example, Mirny–Vostok. Since dunes are the result of cyclonic winds, their orientation varies widely

rather uncertain; the Antarctica contours are not sufficiently reliable to allow accurate interpolation. However, it is unlikely that the error would exceed 50 per cent for any one of the stations named, and this is sufficiently accurate to show that a gravity component of the wind can rival the pressure gradient component. Assuming an inversion strength $\Delta T = 10°$ C, which is quite moderate for the plateau, and a temperature $T = -30°$ C (that is, summer conditions; the annual mean temperature on the high plateau is about $-55°$ C), then for $\alpha = 1{\cdot}5 \times 10^{-3}$ we obtain $A_k = 6 \times 10^{-4}$ m sec^{-2}. This would be equalled by a pressure gradient of 6×10^{-3} mb km^{-1} at the 700 mb level, which is approximately the pressure height of the Soviet inland stations. Such a pressure gradient is not particularly strong, but one can certainly draw the conclusion that even for very strong gradients the katabatic term cannot be ignored so long as there is a surface inversion of typical strength. Notice that the slope will, for some inland stations, be twice the value adopted above. Moreover, the inversion ΔT can be much larger at times, especially during winter when it may lie between 20° and 30°. During mid-summer months it may be only a few degrees, and the probability of its being destroyed temporarily by cyclonic intrusions is greater, but throughout most of the year there is a well-developed surface inversion for which 10° is a fair representation in the first few hundred metres of height.

If A_k and A_p are comparable, the direction of inland winds can be expected to vary widely from day to day according to cyclonic conditions. A low-pressure movement across the plateau generally brings steeper pressure gradients and also more cloud cover which inhibits the temperature inversion. The wind direction will then tend towards the geostrophic pattern. The wind roses of Fig. 1 show that the inland stations do indeed experience a wide range of wind directions. However, the predominance of the downslope direction means that, averaged over the year, A_k is significantly greater than A_p across the inland regions.

The one exception mentioned earlier is Amundsen-Scott, where the most frequent wind is obviously not in agreement with the general picture. The wind direction appears to be cross-slope or even up-slope, rather than down-slope. According to Dalrymple *et al.*[10] the mean slope of the terrain surrounding the Pole is $(1{\cdot}76 \pm 0{\cdot}26) \times 10^{-3}$, with an up-slope bearing of about 152°. Strong inversions have been registered at the South Pole and it would therefore be phenomenal if a gravity component played no part in the equation of motion. However, it is quite possible that a katabatic wind is obscured by larger influences. Dalrymple *et al.* have given an interesting interpretation of the cross-slope flow at the Pole, summarizing their conclusions thus: "... the air motion in the lower atmosphere is controlled by surface friction, and by geostrophic motion in the free atmosphere above the inversion layer, modified by thermal winds due to horizontal temperature gradients which result from the general slope of the terrain".

The proximity of Amundsen-Scott to the Ross Ice Shelf and the persistent strong cyclone over the Shelf and the Ross Sea are probably important in this case. Comparing the traverse data (Fig. 1, small arrows) from South Ice to the Pole and thence to McMurdo, it seems that a fairly sharp change in wind direction occurs in the region of the Pole. Moreover, the winds on the Shelf are not very different in direction from those on the plateau to the west of the Shelf where they tend to be cross-slope. We are inclined to the view that Amundsen-Scott shares in the influence of the Ross Shelf cyclone, that is, $A_p > A_k$ in this area.

In principle, one should instrument a station to obtain accurate and frequent monitoring of the temperature and wind profiles in and above the surface inversion, along with other meteorological parameters. One could then determine the magnitudes of the several force terms in the equation and observe the actual change in wind speed and direction with respect to the relative magnitudes of the terms. Rarely, if ever, has the full instrumentation been maintained so that a systematic study can be conducted. In our analysis, using chiefly surface data collected at Antarctic stations without much anticipation for the present problem, the approach in pursuing the matter further has been to look for characteristic 'signatures' of a katabatic component, for example, diurnal cycles, sudden onsets accompanied by surging, and correlations of wind characteristics with temperature, pressure and cloud cover. We have transferred much of the available meteorological data to punched cards for computer processing. One result from this approach is described here.

The diurnal variation of katabatic winds at coastal stations is a familiar experience. To see whether this same cyclic behaviour could be detected at inland stations, power spectral analyses have been obtained from wind speed data. The spectral programme was modified from that of Munk *et al.*[11] and computations conducted on an IBM 1620; 32 periods were used for 0·5–16 days. To test the programme it was run on a year's data (6-hourly observations, 1958) from Mirny, which is a known katabatic-prone environment.

Fig. 2 shows the power spectrum for Mirny for a range of periods 0·5–5·5 days. The dominant broad peak centred at about 3·5–4·0 days presumably represents the average time lapse between successive cyclonic events and is not of interest in the present analysis. The Pionerskaya spectrum shown in the same figure, which is also based on a full year of 6-hourly data, shows the same 'cyclonic' peak.

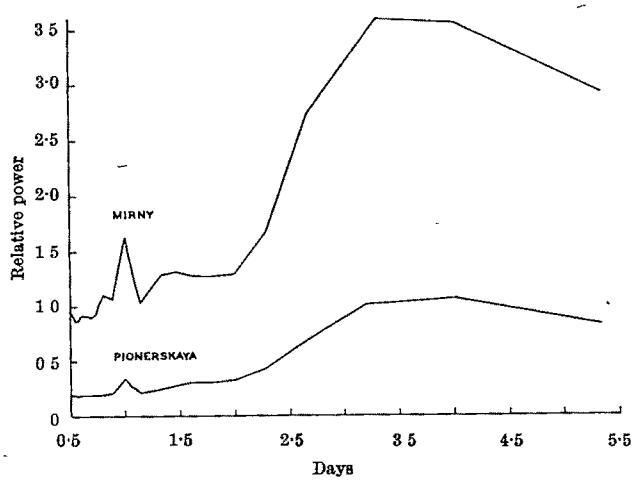

Fig. 2. Spectra of one year's data (6-h observations, 1958)

More important is the occurrence of the 1-day peak on both the Mirny and Pionerskaya spectra. Its amplitude relative to background is about the same for both stations, but its amplitude relative to the cyclonic peak is rather smaller for Pionerskaya, that is, the cyclonic influence on wind speed is relatively more important at the inland station, as would be expected.

Thinking that the diurnal variation inland ought to be more pronounced for near-summer months, as it certainly is on the coast, we have also derived power spectra for either the three months January–March or October–December, 1958. (This is not an ideal choice for 'summer'; it was made because of the availability of an unbroken sequence of data.) The amplitude of the daily cycle of insolation decreases as winter approaches, and in fact falls essentially to zero for stations within the Antarctic Circle. The incidence of cloud and storm is also greater in winter, emphasizing the cyclonic peak in the spectrum. For these reasons, to obtain the most sensitive detection of any

diurnal component which exists far inland, we have used only the summer data for Komsomolskaya, Vostok and Sovietskaya.

The summer spectra for four stations are shown in Fig. 3 on an expanded time-scale covering the periods 0·5–2·0 days. As anticipated, the 1-day peak is now more pronounced on the Pionerskaya spectrum, compared with background. Komsomolskaya shows an unmistakable diurnal cycle, and in the case of Sovietskaya some diurnal effect is at least credible. Vostok is the least convincing. There is a slight hump at about 1 day but a similar hump occurs at about 1·4 days. (Actually several of the spectra show minor peaks at ~1·3–1·6 days. It is not known whether this is fortuitous, an artifact introduced by the particular power spectral programme used, or real. The spectrum from Roi Baudouin, among others, also shows this.) If Vostok has a genuine diurnal variation it would probably be revealed by concentrating on strictly summer months, say December and January. All the spectra, when extended beyond 2 days, show the cyclonic peak.

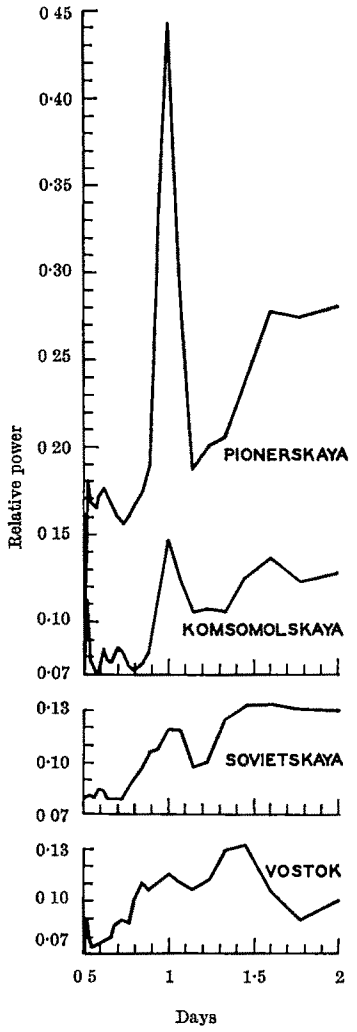

Fig. 3. Summer spectra (January–March or October–December, 1958). (Note that Komsomolskaya and Pionerskaya are on the same scale)

There is, of course, one point in Antarctica where no daily cycle of insolation occurs (ignoring any preferred direction due to the plateau surface slope). This is the South Pole itself, where the Sun maintains the same elevation throughout any one day. We have derived the power spectrum of winds recorded at Amundsen-Scott but have failed to find any trace of a 1-day peak, even though (1) the average wind speed considerably exceeds that at Komsomolskaya, Vostok and Sovietskaya; and (2) the cyclonic peak (~4 days) is again clearly evident. This implies that, not only is the South Pole lacking its own 'cyclic driving function', it is also uninfluenced by diurnal variations which must exist in the drainage of wind from other regions, for example, between the Pole and the 4,000 m summit of the plateau.

The significance of the above observation is that one should not regard the high plateau as a 'breeding ground' from which gravity winds drain radially outwards across the rest of the continent. Rather, the wind is generated locally, as in the case of glacier and valley winds, according to local conditions of slope and inversion, and its continued flow downstream depends wholly on the existence of similar favourable generating conditions downstream, not on the inertia of the air mass. Other observations, such as the very limited offshore penetration of the coastal katabatic wind (< 10 km) and the sensitive response of wind direction to small-scale changes in surface contours, also indicate that the scale of the katabatic process is quite small. We have also found that variations in the wind speed at the inland stations, Komsomolskaya, Vostok and Sovietskaya, show very little interdependence. These investigations will be discussed more fully elsewhere; for the present it is sufficient to note that the absence at the South Pole of a diurnal influence from other parts of the plateau is quite plausible. (It would be interesting to determine where, between Amundsen-Scott and the plateau summit, a diurnal component begins to manifest itself.)

The main conclusions from this work are: (1) a compilation of all available surface wind data from eastern Antarctica shows that the predominant direction of wind drainage is generally consistent with an interpretation in terms of katabatic flow, even where surface slopes are $\sim 10^{-3}$. Remaining uncertainties are due chiefly to poor information on surface contours. (2) Notable exceptions to downslope flow, all coastal, are due to the location of stations offshore, beyond the range of significant katabatic effect. (3) Drainage into the Lambert Glacier and away from the high ridge where the Soviet inland stations are located are two notable examples of localized flow specific to the pattern of surface contours. (4) The effect of pressure gradients due to cyclonic development is very marked, especially inland, but it is not sufficient to obscure the downslope flow over a prolonged period of observations. (5) The diurnal cycle of wind speed, which is a characteristic feature of coastal katabatics, can be traced to inland stations also, using methods of power spectral analyses. (6) No diurnal variation has been detected at the South Pole.

Meteorological data have been drawn from many sources, too numerous to quote individually. We thank the various national Antarctic expeditions represented by the stations on Fig. 1 for their help. The co-operation of the National Weather Records Center, Asheville, N.C., is particularly appreciated. This work was supported by the Office of Antarctic Programs, National Science Foundation, grant *GA*–28.

LETTERS TO THE EDITOR

ASTRONOMY

Prediction of the Dates and Intensities of the Next Two Sunspot Maxima

THERE is still no satisfactory method of predicting sunspot activity beyond the current cycle, but two recent papers have provided new evidence that sunspot activity may be controlled by the positions of the planets. This possibility was discussed more than 50 years ago by Brown[1], and later by Schuster[2], and was adopted as a basis for prediction by others. The recent evidence has been provided by Jose[3] and by Wood and Wood[4]. Jose[3] has shown that the rate of change of the angular momentum of the Sun about the centre of mass of the solar system exhibits a 178-year periodicity which can plausibly be correlated with sunspot activity. Jupiter and Saturn are the planets mainly responsible. Wood and Wood[4] have suggested that the rate of change of angular acceleration of the Sun, which is controlled mainly by the inner planets, shows resemblances in detail to the sunspot numbers. These new results, although not immediately useful in predicting solar activity, do point towards the conclusion that variations in solar activity have a causal basis. If so, an empirical law for the variation of sunspot numbers should eventually be found.

Dates of sunspot maxima and minima. In an article in 1963 I suggested predicting the dates of solar maxima and minima by means of a seven-cycle recurrence tendency in the rise-time t_R from minimum to maximum activity, and a similar recurrence tendency in the quantity t_R/T, where T is the total cycle-length.

The 'official' date of the 1964 sunspot minimum is not yet known because it depends on 12-monthly running means, but it seems very likely to have been in August or September 1964. This is reasonably close to the value predicted by the seven-cycle recurrence method[5]; so the method has not been invalidated, and can be applied again to give revised dates for the next sunspot maxima and minima.

The values found by this method for the rise-time t_R in each of the next two cycles (cycles 20 and 21) are 3·4 years and 3·8 years respectively, and the corresponding values for t_R/T are 0·34 and 0·36 respectively. If the 1964 minimum is taken at 1964·7, the predicted dates for the next two sunspot maxima are 1968·1 and 1978·5, and for the next two minima, 1974·7 and 1985·3.

Although Jose's paper[3] is primarily concerned with long-term solar activity, he gives predictions for the dates of the next two maxima, namely 1967 and 1984. The predictions in the previous paragraph give no indication of the very lengthy cycle implied by Jose's date of 1984 for the maximum of cycle 21. In another recent paper, Bell and Wolbach[6] apply Danjon's formula, based on the brightness of the eclipsed Moon, for predicting the dates of sunspot minima. They obtain 1974·9 and 1985·7 as the dates for the next minima: these agree well with the predictions in the preceding paragraph, 1974·7 and 1985·3.

Intensities of sunspot maxima. The maximum smoothed monthly sunspot number in each cycle, R_m, shows wide variations with little sign of regularity[7]. We require to find a parameter which depends on R_m, but remains fairly constant. In the previous paper[5], the parameter chosen was $R_m\, t_R^2$, which usually has a value near 1750 (if t_R is in years); and Xanthakis[8] has adopted rather a similar approach, suggesting that $R_m \simeq 81 + 0{\cdot}1\,(t_R - 6{\cdot}25)^2$, with some corrections which he specifies. In both these treatments, however, the exceptionally strong maximum in 1957 has to be excluded as a freak. It seems better to devise an expression which includes the 1957 maximum.

The relation previously suggested, namely $R_m\, t_R^2 \simeq 1750$, has therefore been modified by subtracting a term strongly dependent on R_m, so as to destroy the uniqueness of the 1957 maximum, and by changing $R_m\, t_R^2$ to $(R_m - 16)\, t_R^2$, which keeps the numerical value within narrower limits. On inserting values of R_m and t_R for the past ten cycles, back to the year 1860, we find.

$$(R_m - 16)\, t_R^2 - 10^{-5}\,(R_m - 100)^4 \simeq 1401 \qquad (1)$$

with a maximum error of only 70, that is 5 per cent, on the right-hand side. Equation (1) is satisfied by all the ten sunspot maxima since Wolf introduced the concept of sunspot relative number in 1848. Some of the earlier cycles do not satisfy equation (1), but the values of t_R and R_m (particularly the latter) are of doubtful accuracy in the years prior to 1848. Nevertheless the success of equation (1) in future cycles cannot be guaranteed.

Fig. 1 shows the variation of R_m with t_R given by equation (1), with the values from the past ten cycles[7] plotted as circles. The observed values are remarkably close to the curve in Fig. 1, thus strongly indicating a causal link between t_R and R_m. Indeed, Fig. 1 may be just as good as many of the empirical relationships which have in other subjects served as forerunners to the development of true physical laws.

Fig. 1 is not ideal for use in predicting R_m, because two values of R_m are possible if t_R is between 3·3 and 3·6. However, since only one of the ten observed values lies on the upper branch of the curve (above $R_m = 170$), the lower part can be regarded as normal and is to be preferred for prediction. If the value of t_R already obtained for the present cycle, 3·4 years, is correct, Fig. 1 suggests that the highest monthly smoothed sunspot number at the maximum in 1968 will be about 140 (with $R_m = 190$ as a less likely alternative if the upper part of the curve applies). If $R_m = 140$, the present cycle may resemble the cycles with maxima in 1870 and 1947, and solar activity may, at maximum, reach the level prevailing in late 1959.

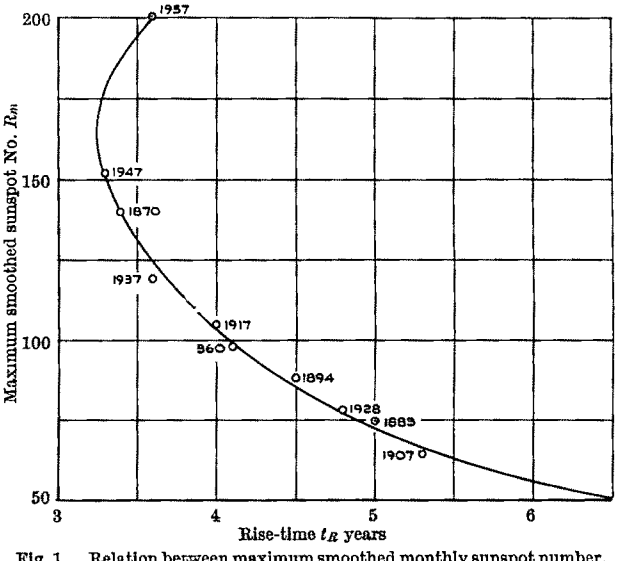

Fig. 1. Relation between maximum smoothed monthly sunspot number, R_m, and rise-time, t_R. ———, Values given by equation (1); ○, actual values in year shown

If the rise-time in the subsequent cycle is 3·8 years, the maximum R_m in 1978 should be about 110.

The predictions may therefore be summarized as follows:

	Cycle 20	Cycle 21
Date of maximum sunspot number	1968·1	1978·5
Intensity of maximum, R_m	140	110
Date of subsequent minimum	1974·7	1985 3

The validity of the prediction methods used here is of course disputable, and there can be no certainty that the predictions are even approximately correct. However, it is certain that the problem of predicting future sunspot numbers cannot be shirked, because the lifetimes of near-Earth satellites[9] are controlled by upper-atmosphere density, which is strongly affected by solar activity. The theory of satellite lifetime estimation cannot be placed on a sound basis until better predictions of solar activity are available, and the prediction of the date and intensity of the next sunspot maximum is also a matter of practical importance. For example, the U.K.3 satellite is intended to fly in a circular orbit at a height of 500 km, and its lifetime in orbit would be reduced by a factor of up to 10 if, at the time of launching (probably 1967), sunspot numbers were very high rather than slowly climbing towards a low maximum. As a second example, the *Echo* 1 satellite would probably not survive a vigorous sunspot maximum, but could last for 10 years longer if the next maximum is very weak. Plans are being made for geodetic triangulation programmes utilizing *Echo* 1, and the date of its decay affects the planning. For these and various other practical reasons (see, for example, refs. 5 and 10), the prediction of sunspot numbers must be attempted, and out of the chaos of discredited methods a correct one may well emerge.

ASTROPHYSICS

Lightning, Solar Flares and Radio Galaxies

In 1925, when it was still believed that a potential of $n \times 10^9$ V was necessary to cause a lightning flash[1a], C. T. R. Wilson put forward the suggestion that the soft cosmic rays up to about 10^9 eV might be accounted for by runaway electrons in thundercloud fields[1b]. When it was pointed out that a lightning flash can occur with a total thundercloud potential of $n \times 10^7$ V (refs. 2[a,b]), the suggestion ceased to have much significance as applied to thunderclouds. However, in presenting a paper on these long leader strokes at the Belfast meeting of the British Association in 1952, I pointed out[2c] that the Wilson mechanism might apply in the much longer cosmic electrical discharges, in which relatively large electric fields must be built up by the short-circuiting of these much more extensive electric fields by the leader stroke of such discharges as solar flares.

In an earlier communication[2d], it was emphasized that temperatures of the order of 10^8 °K must be reached in these last electrical discharges, and in a later communication[2e] it was pointed out that observational evidence had actually been obtained for the association of such temperatures with outbursts of solar flares.

The velocity of the jets of gas generated by these discharges is of the same order as that of the thermal velocities of the ions, namely, about 10^8 cm/sec, and thus accounted for the delay of about 1 day between the solar outburst and the main magnetic storm at the Earth. The associated electron velocities will be about 40 times this value or about 4×10^9 cm/sec, and it is now suggested that some of these electrons become the runaway electrons which account for the arrival at the Earth of a soft cosmic ray component about half an hour after the observed solar outburst. Their average speed is thus about 10^{10} cm/sec, so they would only require to be accelerated by a factor of about 2 in the solar electric field.

This consideration would confirm the view arrived at from an investigation of cometary phenomena[2f] that the polarity of the solar field is the same as that of the thunderstorm field; that is, the regions farthest out in the gravitational field become positive.

This view of the existence of two major velocities of propagation of two different types of activity, a high-speed electron component and a plasma jet, has interesting possible applications in the investigation of radio galaxies, in which the same two components may be expected to occur. Observations on the gas velocities made by Seyfert[3] of about 4×10^8 cm/sec suggest the existence of plasma jets at temperatures of about 4×10^8 °K (ref. 2[g]). Associated with these we should expect to find active haloes due to the runaway electrons from the main discharges and reaching dimensions of the order of ten times the latter. This is just what is observed, and in the case of Virgo *A* (*NGC* 4486) "the general direction of the extension is the same as that of the 'jet' which optical observations have shown issuing from the nucleus of *NGC* 4486" (ref. 4*a*). Shain writes in the same contribution that "when angular sizes of a number of radio galaxies are determined, any optical search for associated galaxies must extend to galaxies having one-tenth or less of the radio diameters"[4b].

PHYSICS

Formation of Straight Whiskers on Sublimating Single Potassium Chloride Crystal

Nannichi has reported on the formation of silicon whiskers on a sublimating surface[1]. The specimen had in this case been kept at least 200 h at 1,000°–1,250° C in an initial vacuum of less than 10^{-8} torr. The whiskers were bent and whirled but their tips were at the height of the original surface. Matter is transported away from the neighbourhood of certain places by thermal erosion so that what is left is thin enough to be called a 'whisker'.

In an investigation of the effect of annealing on the cleavage surface, straight whiskers were found on single potassium chloride crystals annealed at 600° C for 5–23 h in a vacuum of about 0·1–1 torr. They were first found lying on the crystal surface (Fig. 1). A closer investigation revealed that there were also whiskers at right angles to the (100) surfaces (Fig. 2). The white dots marked with arrows in Fig. 1 are due to upright whiskers.

Different surface features are formed during the heat treatment[2,3]. Abnormal features, for example plateaux,

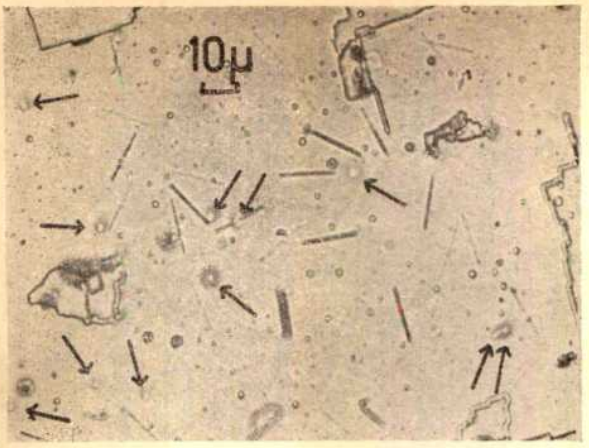

Fig. 1. Whiskers of about the same length, but of different thickness, lying on an annealed (5 h at 600° C) potassium chloride crystal. The white spots marked with arrows are upright whiskers

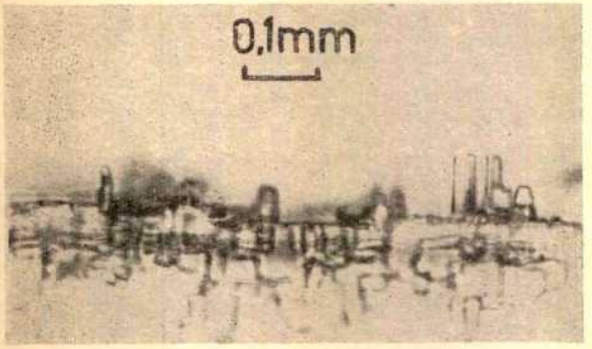

Fig. 2. Whiskers and pillars on an annealed (23 h at 600° C) potassium chloride crystal

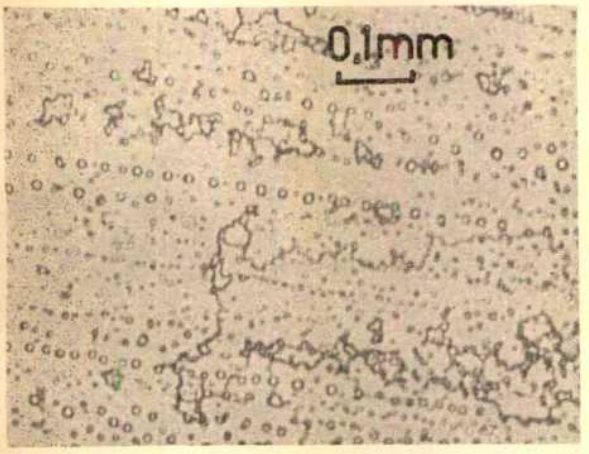

Fig. 3. Pillars formed in rows parallel to the cleavage steps on an annealed (5 h at 600° C) potassium chloride crystal

are traceable to impurities like silica compounds[4]. These cover the original surface in some places and inhibit sublimation. The widening of thermal etch pits is in certain places slowed down by these impurities. When a pit deepens the sublimation steps reach the edge, thus forming steep sides. When the pits combine around a poisoned place, pillars of different cross-sections are formed. The pillars are sometimes formed in rows parallel to cleavage steps (Fig. 3). This indicates that the impurities may easily attach themselves to some critical places formed in the cleavage process. The sides of the pillars are not perfect and thus sublimation takes place on them. The less perfect sides sublimate more rapidly and thus the thinning pillar seeks for itself a position with more perfect sides. Whiskers are known to sublimate slowly[5,6] because of their perfect sides. Thus the pillars formed with better sides are left on the sublimating surface, becoming longer and thinner until totally sublimated. Because the whiskers in Fig. 1 are nearly of equal length they have fallen down after the heat treatment.

The part played by impurities (higher carbohydrates originating from the vacuum pump and greased joints[7]), adsorbed on advancing sublimation steps, which could govern the steepening of the sides of the pits, is not clear. It is probable that they may be disregarded; all that is needed is for poisoned places to lie on the original cleavage surface, and for the whiskers formed to have a high thermal strength.

I thank Prof. M. Kantola for extending the facilities of the laboratory. This work was supported by Suomen Kulttuurirahasto.

Estimation of Moisture Content by Neutron Scattering: Effect of Sample Density and Composition

SINCE it was first developed about 1950[1,2] the technique of estimating moisture content by neutron scattering has been extensively used in the determination of soil moisture. In recent years, workers in several countries have extended the method to other materials[3], utilizing in some instances the surface probe technique developed by Pawliw and Spinks for concrete[4]. The basic assumptions in all these measurements have been (*a*) that the thermalizing power of hydrogen is so great in comparison with other elements that the slow neutron flux measured by the instrument can be ascribed solely to the hydrogen present in the sample[5], and (*b*) that there is a unique relationship between hydrogen content and slow neutron flux except when elements of high capture cross-section for neutrons are present[3a].

We have examined the response of a commercial surface-type instrument to changes of moisture content in a number of building materials. Fig. 1 shows the results obtained with four specimens. These were (*a*) a concrete made with Portland cement, sand and basalt, with oven-dry density 2·23 g/c.c., (*b*) a concrete made with Portland cement, sand and expanded shale, with oven dry density 1·41 g/c.c., (*c*) foamed Portland cement; oven dry density 0·99 g/c.c., (*d*) foamed Portland cement; oven dry density 0·50 g/c.c. The thermal neutron count is expressed as a fraction of that obtained on a standard paraffin wax block ('relative thermal neutron count'). The total water content includes bound water. It can be seen that the curves are essentially parallel, but are displaced from one another to such an extent that the same neutron count corresponds to much more water in specimen *d* than in specimen *a*; for example, at a relative neutron count of 0·25, the water contents vary almost in the ratio of 2 : 1. The relative positions of these curves suggest that the density of the material has a large effect on the response, although the coincidence of the curves for samples *b* and *c* shows that density alone is not the deciding factor. A similar density effect has been reported recently by

Lachaud in connexion with an attempt to use neutron scattering to estimate the bitumen content of road surfacing mixtures[6].

From these observations it appears that the thermalizing power of atoms other than hydrogen cannot be neglected and that it is necessary to consider both the density and the type of the other atoms present.

It seems that the assumption of the overwhelming thermalizing power of hydrogen has arisen from considerations at thermal and near-thermal levels where the microscopic slowing-down power (defined as $\xi\ \sigma_s$ where ξ is the average logarithmic energy loss of the neutron per collision and σ_s the scattering cross-section of the nucleus concerned) is very much greater for hydrogen than for other atoms. For example, at 0·025 eV the ratio of the microscopic slowing-down powers of hydrogen and oxygen is 72 : 1 and of hydrogen and carbon 45 : 1. However, σ_s varies with neutron energy and, although ξ is approximately constant for each atom below 100 keV, above this energy there is a reduction in its effective value as the scattering becomes anisotropic. The percentage change in ξ is greatest for hydrogen but is of a similar order of magnitude for all of the atoms with which we are concerned here, that is, the differences in this latter effect for the various atoms are sufficiently small for them to be neglected in calculations such as those which follow. Fig. 2 shows the variation of the total cross-sections of hydrogen and of oxygen with neutron energy. For these elements the total cross-section is essentially the scattering cross-section. Although the cross-section of hydrogen is much larger than that of oxygen at very low neutron energies, the difference diminishes as the neutron energy increases until, above 3 MeV, the cross-section of oxygen actually exceeds that of hydrogen.

In these higher energy ranges, where the effect of atoms other than hydrogen is appreciable, a significant proportion of the total number of collisions needed to cause thermalization occurs; slightly more than 20 per cent occur between 5 MeV and 100 keV. From the data in Table 1 it appears that over this energy range the hydrogen content of a concrete specimen (*b*) may be responsible for only about half the total slowing down. At lower energies the hydrogen will have a proportionately greater effect, but the contribution of the other atoms will still not be zero. For example, between 100 keV and 1 eV the oxygen content of this specimen should produce about one-fifth of the slowing down produced by hydrogen. Consequently it is only to be expected that any major change in density or in the composition of the non-aqueous part of the specimen will change the slow neutron flux corresponding to a given moisture content.

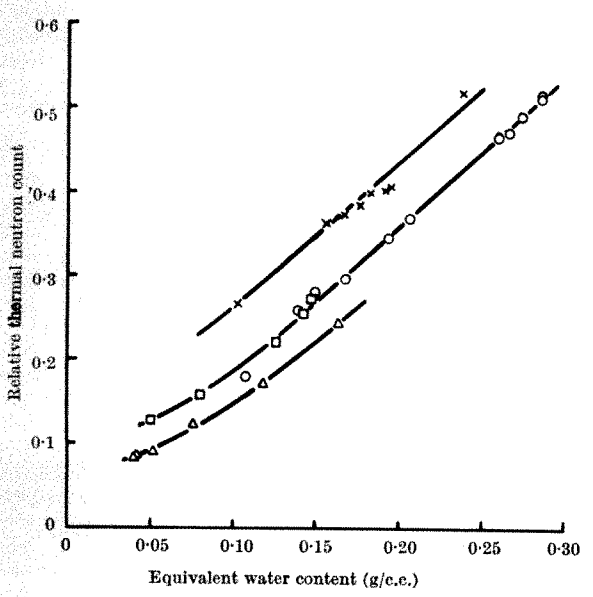

Fig. 1. Relationship of neutron count to water content for different materials. ×, basalt concrete, 2·23 g/c.c., *a*; □, shale concrete, 1·41 g/c.c., *b*; ○, foamed cement, 0·99 g/c.c., *c*; △, foamed cement, 0·50 g/c.c., *d*

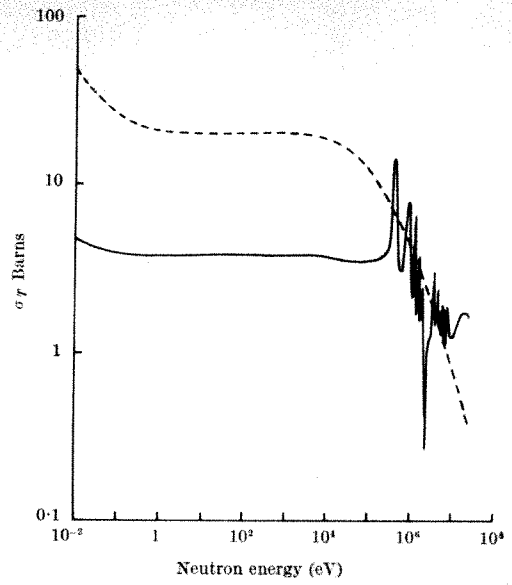

Fig. 2. Variation of total cross-section of hydrogen (broken line) and oxygen (solid line) with neutron energy

Our experimental data, however, suggest that the initial collisions of the fast neutrons (for example, between 5 MeV and 100 keV) may have an even greater influence on the thermal neutron flux than would be expected from the foregoing argument. The slow neutron flux from a given source should be directly proportional to the sum of the microscopic slowing-down powers of the components of the test material suitably averaged over the whole energy range from emission (5 MeV) to thermal energies (say 0·025 eV).

Table 1. Contributions of the Various Components of Specimen *b* (Expanded Shale Concrete, Water Content 0·05 g/c.c.) to Neutron Energy Loss Between 5 MeV and 100 keV

Element	Atoms per c.c. × 10^{-20} (N)	ξ	Mean scattering cross-section 5 MeV–100 keV (σ_s) barns	Microscopic slowing-down power 5 MeV–100 keV $\xi \times \sigma_s$	Macroscopic slowing-down power 5 MeV–100 keV $N \times \xi \times \sigma_s$
H	34·4	1·000	5·7	5·7	196
C	2·3	0·158	2·8	0·44	1·0
O	261·5	0·120	5·2	0·62	162
Al	9·7	0·072	3·4	0·25	2·4
Si	94·2	0·070	3·3	0·23	22
Ca	22·7	0·049	2·3	0·11	2·5

Table 2. Observed and Calculated Relative Thermal Neutron Counts at Different Moisture Levels

Observed	Calculated		
	Specimen *b*	Specimen *c*	Specimen *d*
0·127	0·127	—	0·128
0·179	—	0·172	0·179
0·266	0·259	0·226	0·250

We have calculated the theoretical instrument response on this basis using the mean scattering cross-section for the range 5–100 keV, that is, calculating as if the relative cross-sections remain at their average value over the first 20 per cent of the thermalizing collisions for all subsequent collisions. Since the constant of proportionality is not known, one was selected arbitrarily so that the calculated value for specimen *b* at a moisture content of 0·05 g/c.c. agreed with the observed value. The results are given in Table 2, from which it can be seen that the correspondence between observed and calculated values is good, that is to say, the observed slow neutron flux varies as if it were greatly influenced by the initial collisions of the fast neutrons during which the scattering cross-section of

hydrogen is of the same order of magnitude as that of many of the common atoms.

Agreement to within 20 per cent has been obtained between the calculated and observed responses from a number of other materials containing various amounts of water or other source of hydrogen, namely, wood, sand, sand–sugar mixtures, and gypsum, and hence the same dependence of the thermal neutron flux on atoms other than hydrogen has been found over a range of composition and density. Allowance must, therefore, be made for this if neutron scattering is to be successfully used for moisture estimations in materials of density or composition different from that with which the instrument was calibrated.

Propagation of Stress Pulses across the Interface between Two Immiscible Liquids

Previous experiments have been described by me and others[1,2] in which pulses of compression and of tension have been propagated through a liquid column. This communication reports some experiments in which stress pulses were propagated across the plane boundary between two liquids which do not mix.

For this purpose, a cylindrical steel tube was used to contain the liquids. This tube was 3 ft. long, internal diameter 7/8 in. and external diameter 1·25 in. It was fitted with a steel piston at its lower end and a pressure pulse was generated in the liquid by firing a lead bullet of 0·22 in. calibre so as to strike the lower end of the piston normally at its centre. The pressure changes in the liquid were measured by means of a horizontal pressure bar mounted in a 'porthole' below the liquid surface.

In this series of experiments, water occupied the steel tube to a level of 5 cm or so above the pressure bar; about 50 cm³ of transformer oil were then added. If we refer to the water and the oil as media (1) and (2), respectively, their acoustic impedances are $R_1 = 1{\cdot}49 \times 10^5$ g cm^{-2} sec^{-1} and $R_2 = 1{\cdot}28 \times 10^5$ g cm^{-2} sec^{-1}. Thus, for a stress pulse incident on the water–oil boundary from the water below we have the results:

$$\text{Transmissivity, } t_{12} = \frac{2R_1}{R_1+R_2} = 1{\cdot}076$$

$$\text{Reflectivity, } r_{12} = \frac{R_2-R_1}{R_1+R_2} = -0{\cdot}076$$

Similarly, for a pulse incident on the boundary from the oil, we have:

$$t_{21} = \frac{2R_2}{R_1+R_2} = 0{\cdot}924$$

$$r_{21} = \frac{R_1-R_2}{R_1+R_2} = 0{\cdot}076$$

Let us now consider what happens when a compressional pulse, of peak pressure P_t, is incident on the interface from the water. The pulse transmitted into the oil then has a peak pressure of $P_t = 1{\cdot}076\ P_t$, and at the upper free surface of the oil it is reflected as a tension pulse of peak value $P'_t = -P_t = -1{\cdot}076\ P_t$. When this downgoing pulse in the oil reaches the interface a tension pulse of peak value $P''_t = 0{\cdot}924\ P'_t = -0{\cdot}995\ P_t$ is propagated down into the water. In these experiments P_t is of the order of 100 atm. so that the peak tension P''_t to be expected in the water is of the same order. All this reasoning is based, of course, on the assumption that no cavitation occurs.

In a number of records taken the maximum tension recorded in the water was about 7 atm. This is the same as the value obtained when the steel tube contained water only and reported earlier by Rees and me. The most surprising thing is that it is possible for a tension wave to be propagated at all across a well-defined plane interface like that between these two liquids. Certainly the result is surprising from a 'macroscopic' view of stress-wave propagation and brings to mind Hopkinson's[3] celebrated work on the pressure-bar. In these experiments Hopkinson used a pressure-bar which had a detachable end-piece wrung to one end and he found that compressional pulses could be transmitted across the plane boundary between the bar and end-piece but that tension pulses could not. The present arrangement is rather similar in the sense that the water column is like the pressure-bar and the oil column like the end-piece in contact with it. These experimental results certainly emphasize the fact that pulse propagation in liquids is more accurately described by means of a 'microscopic' approach, that is, in terms of the motion of the individual particles of the medium.

GEOLOGY

Pumice from the South Sandwich Eruption of March 1962 reaches New Zealand

On March 14, 1962, H.M.S. *Protector* encountered an extensive raft of large and small pumice fragments in the neighbourhood of Zavodovski Island in the South Sandwich Islands[1]. It is believed that this pumice was erupted on March 5 from a submarine volcano which forms a shoal, minimum depth 15 fathoms, 55·9° S, 28·1° W., lying some 35 miles north-west of Zavodovski Island. Towards the end of 1963, fragments of pumice up to 3 ft. in diameter were noticed washed up on the south-west coast of Tasmania and these have been tentatively correlated with the South Sandwich occurrence[2].

On January 24, 1964, H.M.N.Z.S. *Pukaki* collected pea- and marble-sized pieces of pumice floating in abundance south of Macquarie Island at 60° S., 160° E., and these, together with a larger block carrying barnacles, were forwarded to the University of Otago. During the southern autumn and winter of 1964 abundant blocks of pumice were noticed at Mason Bay, on the west coast of Stewart Island off the south tip of South Island of New Zealand and in the general area of Foveaux Strait, which separates Stewart Island from South Island. In August of the same year abundant blocks of pumice up to 1 ft. or more in diameter were observed by us on the western shores of Bluff Peninsula in Foveaux Strait.

Since then we have been given numerous specimens of identical pumice that were collected at similar or even earlier dates, for example, one large block said to have been collected 20 miles south of Dunedin in January, 1964, and two large blocks, representative of many found during March 1964, in Lyttleton Harbour, Banks Peninsula, about 330 miles north-east of Bluff on the east coast

of the South Island. Furthermore, a reliable observer reports pumice on Foveaux Strait beaches as early as August 1963. Late in September 1964 many pieces were collected on the west coast of the South Island near Greymouth, 340 miles north of Foveaux Strait. No pumice had been found on the same beach previously, and furthermore, like the Bluff Peninsula blocks, those from Greymouth, carried live colonies of the barnacle *Lepas anatifera* (identified by Dr. E. Batham of the Portobello Marine Biological Station, University of Otago). The approximate date of arrival on the beach is thus clear.

By December 1964 fragments, often carrying live colonies of *Lepas*, began to arrive in abundance on many South Island beaches, both on the east and west coasts (for example, Waimairi Beach near Christchurch; Spit, Warrington and Akatore beaches near Dunedin; Big Bay, Jackson Bay and Karamea on the West Coast) while a block of about 1·5 ft. diameter was observed on D'Urville Island at the western entrance of Cook Strait separating the North and South Islands of New Zealand. Previous searches of Warrington Beach had failed to yield any pumice although considerable quantities of pumice had been reported from Waimairi Beach about one year previously—a statement not incompatible with the collection from Lyttleton Harbour. In places, for example, Akatore, January 1965, pea-size and smaller (very coarse sand) grains have been noticed floating like scum on the water.

Like the South Sandwich materials the New Zealand specimens are pale grey to whitish in colour, with occasional darker streaks and inclusions. On being broken open, a number of them give off a distinct sulphurous smell, as was also recorded by Gass *et al.*[1]. The pumice is intensely vesicular consisting of a fine, delicate mesh of glass with larger cavities that not uncommonly contain a filigree of glass fibres. They contain small scattered crystals of several minerals.

The refractive index of the pumice in the South Island and *Pukaki* collections shows little variation. Determinations on about 20 fragments (for example, *OU* 19796–197808) range from 1·493 to 1·496 ± 0·002, though usually near 1·493. This is in fair agreement with the figure of 1·496 ± 0·002 given by Gass *et al.* for floating pumice collected near Zavodovsky Island in March 1962. Specimens from near the original site, forwarded to us by Dr. P. G. Harris, have refractive index 1·494 ± 0·002.

The commonest phenocrysts and microphenocrysts are plagioclase which often shows oscillatory zoning, the maximum variation observed being An_{70} to An_{40}. Hexagonal bipyramids of quartz, 1–2 mm in diameter, are not uncommon in the pumice grounded on New Zealand beaches, and although not mentioned in the account of Gass *et al.*[1], they do occur in the specimens forwarded to us by Dr. Harris. The most abundant mafic mineral is greenish-brown hypersthene in prisms up to 2 mm long containing fluid inclusions and acicular apatite. The refractive index, γ, is commonly in the range 1·720–1·733 ± 0·002, the crystals sometimes being noticeably zoned. Augite (β 1·704–1·706 ± 0·002) is subordinate to hypersthene and occurs as scattered green prisms. Magnetite is also present as scattered grains, often partially included in the microphenocrysts of pyroxene. The assemblage of mafic minerals in the drifted pumice is indistinguishable from that in the South Sandwich pumice provided by Dr. Harris. Small xenoliths, including one of hornblende hornfels, were observed. Another feature common to the South Sandwich and South Islands specimens is the relative abundance of halite cubes and other soluble salts even in the interior of quite large blocks.

The data presented here firmly establish the correlation of the drift pumice with that of the South Sandwich eruption. In contrast it may be noted that the refractive index of the glass, the relatively anorthite-rich range of plagioclase compositions and the presence of quartz, contrast rather sharply with the sub-recent pumices of the North Island of New Zealand[3].

To reach Foveaux Strait the first flush of pumice to arrive in abundance has travelled a net distance of about 7,000 nautical miles in 850 days in the West Wind Drift at an average net rate of about 8 nautical miles per day. The earliest South Island drift pumice we have checked microscopically has travelled the distance in 680 days at a rate of 10 miles per day, while some pumice, presumably from the same eruption, would appear to have completed the journey in about 530 days at an average net rate of about 13 nautical miles per day. The drift rate for the coarse and fine pumice encountered by H.M.N.Z.S. *Pukaki* and for the 1963 groundings on Tasmania is also about 10 miles per day. Since then pumice has been more slowly distributed to east coast beaches by the coastal Southland current[4].

Previous data on the velocity of the West Wind Drift appear to be scanty, but Deacon[5] notes the eastward drift of bottles and of jetsam at about 8 miles a day. Russell[6] gives a list of recent papers that reported a rapid daily drift; he notes numerous examples from the southern seas with drift rates of 11–13 miles a day. It may be noted, in comparison, that Richards[7] has shown that pumice from the 1952 eruption of Isla San Benedicto, off the coast of Mexico, travelled to points as far westward as the Marshall Islands at rates ranging from an average of 4·7–14·7 nautical miles a day, while Krakatoa pumice drifted westwards across the Indian Ocean at rather similar rates.

In addition to the light they throw on the drift of materials floating in the surface layers of the sea, these instances provide graphic evidence of the manner in which certain pyroclastic materials can be transported for very great distances, ultimately no doubt to be incorporated in sedimentary rocks deposited remote from the site of any volcanic activity.

We are grateful to many individuals for specimens and information; in particular, Dr. E. Batham, Mr. J. W. Brodie, Mr. J. D. Campbell, Prof. S. W. Carey, Mr. D. R. Gregg, Mr. W. F. Lindqvist, Mr. W. J. Smolenski, Dr. R. P. Suggate, Dr. W. A. Watters and Mr. D. Young.

Changes in Level of Lake Naivasha, Kenya, during Postglacial Times

Strandlines high above the present levels of three small lakes in Kenya provide some of the earliest-recognized evidence for past climatic changes in tropical Africa. The terraces above Lakes Nakuru, Naivasha and Elmenteita were studied intensively by Nilsson[1,2] more than 30 years ago, and are one of the major bases on which the pluvial theory of Pleistocene climates in Africa was constructed. Despite later disagreements on the number and interpretation of these strandlines, it is still generally accepted that they provide good evidence for at least one pluvial period (the Gamblian) and two lesser post-pluvial wet phases (the Makalian and Nakuran)[3,4].

The three lakes lie in adjacent closed basins in the Eastern Rift Valley, between latitudes 0° 15′ and 0° 50′ S., and longitudes 36° 0′ and 36° 30′ E. They have fluctuated sensitively during the past 50 years in accordance with

both yearly changes and more long-term trends of rainfall.

In December 1960 and January 1961, Robert Kendall and I raised a 28-m core from the deepest part of Lake Naivasha, a submerged crater near the eastern shore. At that time the crater was 13 m deep, and was almost cut off from the main body of the lake by its slightly elevated outer rim (Crescent Island). During past periods of lower water, the crater must have been completely isolated.

Core analyses of diatoms, pollen, chemistry and mineralogy have been carried out in collaboration with Dr. D. A. Livingstone, and three carbon dates have been provided by the Yale Radiocarbon Laboratory. An extremely rapid average rate of sedimentation has characterized that portion of the history of the Lake covered by the core, the total age of the section being 9,200 ± 160 years. This is insufficient to provide evidence regarding the Gamblian Pluvial, which is believed to have ended 10^3 or 12×10^3 years ago[5], but the core has supplied a very detailed record of changes in this basin during most of the supposed time-span of the Makalian and Nakuran wet phases.

The lower half of the section was much more homogeneous than the upper in gross appearance, chemistry and mineralogy; and the diatom assemblages of this region, though variable, always contained euplanktonic species (for example, *Strephanodiscus cstraea*) as important constituents, together with more littoral forms. These lines of evidence indicate a lake of medium size in which the crater was freely confluent with the main lake. A date of 5,650 ± 120 years before 1950 fixes the end of this relatively stable phase in the history of the Lake.

Metres 14–8·20 represent a second phase, during which the Lake shrank and the crater portion was reduced to a weedy pond. Percentages of organic matter and carbonate were higher in this part of the core, and sharp changes in the diatom assemblages suggested that the crater was isolated from the main lake as far back as the middle of metre 12. This phase was terminated abruptly by a complete drying of the crater basin, as indicated by a partially weathered, impermeable, sandy layer extending from metre 8·20–7·80. The sharp interface between this layer and the underlying lake mud suggests that during this dry period the water table never lay more than 40 or 50 cm beneath the surface (that is, approximately 21·7 m below the water level at the end of 1960). A date of 3,000 ± 60 B.P. has been obtained for the portion of metre 8 just above the dry zone.

The remaining few upper metres of the core were, when wet, very colourfully banded in many parts, and all the analyses suggest a lake the conditions of which were rapidly fluctuating, often more concentrated chemically than it is to-day. This lake was usually (if not always) smaller than it has been in historic times.

These stages of Lake Naivasha are compared in Table 1 with a recent chronology[4] of the post-pluvial wet phases, in which the dates were approximated from cultural evidence and from a presumed relationship between these phases and postglacial climatic events in Europe. The new evidence from Naivasha corresponds quite closely with the previously established picture, but indicates that the latter must be modified in one important respect. The Nakuran wet phase was described from a strandline at Lake Nakuru which Nilsson and others believed equivalent to a Naivasha strandline 23 m above the 1960-level of the Lake. If the core interpretation is correct, the Lake could not have been this high for almost 5,000 years, and the Nakuran wet phase must thus be back-dated considerably. The present investigation produced results which agree with suggestions that there has been a return to wetter conditions in the past 3,000 years, but this shift has been more modest than hitherto supposed.

Table 1. PRESUMED HOLOCENE CLIMATIC SEQUENCE IN EAST AFRICA WITH ESTIMATED DATES (ADAPTED FROM COLE[4]), COMPARED WITH CARBON-14 DATED STAGES OF LAKE NAIVASHA

Climatic phase	Years before 1950 (est.)	Naivasha	Years before 1950 (C^{14})
	0		(0)
Nakuran wet phase		Small, fluctuating lake	
	2,750		3,000 ± 60
Dry interval		Dry	
	4,450	Shrinking	
			5,650 ± 120
Makalian wet phase (2)		Lake larger than at present	
	7,450		
Drier			9,200 ± 160
	9,450		
Makalian wet phase (1)?		(No evidence)	

The core has also provided evidence that more sharply seasonal climates characterized the Naivasha watershed until about 2,500 years ago. Varves were found through most of the section below metre 7, but not above. In most of East Africa to-day the climate is characterized by one rainy and one dry season yearly, but a narrow equatorial belt that includes Naivasha exhibits a more muted seasonality, with two moderately rainy and two moderately dry periods per annum. The more seasonal rainfall pattern at present occurs within 65 km of Naivasha, and no great migration of climatic belts—probably just a slight accentuation of the monsoon, in fact—need be postulated for periods when this more seasonal régime occurred at Naivasha.

Modern trends of total yearly rainfall have not been uniform throughout East Africa. It has been shown that various parts of Kenya alone can follow persistent opposing rainfall trends over periods of 30 years or more[6]. Therefore the possibility cannot be dismissed that the relatively moderate changes in size of Lake Naivasha during the past 9,000 years reflect quite local climatic shifts. Evidence from other investigations in Africa, however, makes this seem unlikely. Two sharp changes in a pollen curve from Mount Kenya[6], 140 km north-east of the Lake, seem clearly to coincide with the onset of the shrinking stage and of the dry period at Naivasha. Changes in the level of the Lake cannot be correlated so closely with a pollen profile from the Cherangani Hills[7], 240 km north-west of Naivasha, but the latter investigation is not contradictory. Farther afield, climates deduced for dated levels at Kalambo Falls[8] and in north-eastern Angola[9], 1,000 and 1,850 km south-west respectively, are consistent with those that could be inferred contemporaneously at Naivasha. Broadly similar climatic trends, although perhaps asynchronous by a thousand years or more, may even be traced during this period in the Chad basin[10], far to the west. These comparisons suggest that widespread climatic phenomena, particularly the warmer temperatures of the climatic optimum, were at least partly responsible for the changes in size of Lake Naivasha.

I thank Dr. S. D. Heron and the Department of Geology at Duke University for assistance with the mineralogical investigations; Dr. Minze Stuiver and his colleagues at the Yale Radiocarbon Laboratory for the valuable absolute dates; and the National Science Foundation for providing financial support for Dr. D. A. Livingstone and myself. This material formed part of a doctoral thesis submitted to the Graduate School of Arts and Sciences at Duke University.

CHEMISTRY

Tetrakis (Triphenyl Phosphite) Nickel (0) as an Initiator of Polymerization at Room Temperature

Organo-metallic compounds in which the metal is in a low (preferably zero) oxidation state, in the presence of a suitable organic halide, can initiate the free-radical polymerization of vinyl monomers[1]. The metal carbonyls and their derivatives, and the hexaphenylisocyano[2] complexes of group VI metals have been most studied from this point of view. Recently we have studied the compound tetrakis (triphenyl phosphite) nickel (0) (TTPN), described in the literature earlier this year[3]; our observations on this material, which shows unusually high activity as an initiator, are reported here. From a practical point of view this derivative has the advantage of possessing a comparatively high stability in the solid state (it melts fairly sharply at 146° C)—an unusual attribute for a material which is an effective initiator at room temperature.

As a ligand, triphenyl phosphite belongs to the same class as carbon monoxide and phenyl isocyanide; however, the double-bond character of the phosphorus to metal bond arising from the back-donation of electrons from the *d* orbitals of the metal to the ligand is much less and consequently the ligand is more readily displaced.

Tetrakis (triphenyl phosphite) nickel (0) was prepared by the reaction of the pure ligand and freshly sublimed nickelocene in boiling benzene under a nitrogen atmosphere, according to the method of Olechowski, McAlister and Clark[3], and purified as described by these authors.

The derivative alone is not an effective initiator of the polymerization of methyl methacrylate at 25° C, but it initiates readily in the presence of a low concentration of a suitable organic halide such as carbon tetrachloride. The dependence of rate of polymerization on carbon tetrachloride concentration is remarkably similar to that observed with the metal carbonyl[1] and phenyl isocyanide derivatives[2]; the rate, almost zero for $[CCl_4] = 0$, at first rises rapidly with increasing $[CCl_4]$ but ultimately reaches a plateau value, so that for $[CCl_4] > 0{\cdot}02$ mole $l.^{-1}$ it is independent of $[CCl_4]$. With nickel carbonyl the limiting rate is reached only at higher values of $[CCl_4]$ (ref. 4).

In bulk methyl methacrylate at 25° C the rate of polymerization is given by:

$$-\frac{d[M]}{dt} = 1{\cdot}02 \times 10^{-2}\,[\mathrm{TTPN}]^{1/2}\ \text{mole}\ l.^{-1}\ \text{sec}^{-1} \quad (1)$$

(M represents the monomer). The free-radical nature of the reaction is indicated by the half-order in initiator concentration in (1) and also by the fact that the kinetic parameter $k_p k_t^{-\frac{1}{2}}$ (k_p, k_t being propagation and termination coefficients, respectively) calculated from mean rates and degrees of polymerization has the normal value for the free-radical polymerization of methyl methacrylate at 25° C. The order in monomer concentration is 1·5 (with benzene as diluent), showing that the monomer enters into the initiation step; this has been found with some carbonyls, for example, molybdenum carbonyl[5]. We believe that a similar mechanism holds in all these systems—the metal derivative reacting with monomer to form a complex which afterwards yields radicals on reaction with the halide.

Tetrakis (triphenyl phosphite) nickel (0) does not show the marked inhibition observed with nickel carbonyl[4], so that the relationship (1) is obeyed over the whole range of concentrations investigated (up to $2{\cdot}9 \times 10^{-3}$ mole $l.^{-1}$). Initiation at 25° C is much more rapid under comparable conditions of concentration than with nickel carbonyl particularly at high initiator concentrations when inhibition in the nickel carbonyl system is very marked. Even at low concentrations the difference amounts to a factor of nearly 100 in the rate of initiation. These results, therefore, are consistent with the view that triphenyl phosphite is a more labile ligand.

Triphenyl phosphite acts as a mild inhibitor of the polymerization, the effect being very small compared to the inhibition by carbon monoxide encountered in the corresponding carbonyl system. (Triphenyl phosphite is not a retarder in these reactions, nor does it affect the free-radical polymerization of methyl methacrylate initiated by azo-*bis*-isobutyronitrile.) This may indicate that the initial reaction of the nickel derivative with monomer is not readily reversible, or that the greater part of the process involves addition of monomer without scission of a triphenyl phosphite ligand.

Use of polyvinyl trichloracetate (PVTCA) as the halide in place of carbon tetrachloride leads to very rapid gelation at 25° C. Thus with $[\mathrm{PVTCA}] = 3{\cdot}84 \times 10^{-2}$ base mole $l.^{-1}$ (weight average molecular weight 88,000) and $[\mathrm{TTPN}] = 6{\cdot}15 \times 10^{-4}$ mole $l.^{-1}$ the gel time is 10 min, approximately. As already shown[6], this implies that radical formation takes place by abstraction of a halogen atom from the halide by the metal derivative, giving an organic radical (for example, $\cdot CCl_3$ from CCl_4) capable of initiating polymerization.

Work is in progress to investigate the effect of changes in the structure of the organic ligand on the activity of these initiating systems.

Effect of Zinc Chloride on the Velocity Coefficients in the Polymerization of Methyl Methacrylate

It is well known that the reactivity of the propagating species in ionic polymerization is greatly influenced by the proximity and character of the gegenions and by complex formation. As a rule, free radical reactions are comparatively insensitive to the nature of their environment, although there are references in the literature to changes in the rate of free-radical polymerizations, and the nature of the polymers formed, which have been attributed to the participation of radicals in complexed forms. The investigation of the structure and reactivity of radical complexes in polymerization is a field which has not been surveyed systematically, but which, nevertheless, may contain interesting features. We have embarked on an investigation of the absolute rate coefficients in the free-radical polymerization of vinyl monomers in the presence of possible complexing agents and report here some results for the methyl methacrylate–zinc chloride system. The only measurements of a similar type recorded in the literature appear to be those of Bamford, Jenkins and Johnston[1], on acrylonitrile in *NN*-dimethylformamide solution in the presence of lithium salts. Kargin, Kabanov and Zubov[2] considered that the presence of zinc chloride during the polymerization of methyl methacrylate affects the microstructure of the polymer, but this finding was not confirmed by Bovey[3]. More recently, Imoto, Otsu and Harada[4] have

investigated the steady-state polymerization of methyl methacrylate in the presence of zinc chloride and have shown that at 60° C the rate of the reaction initiated by azo-*bis*-isobutyronitrile is increased by addition of zinc chloride, the ratio $k_p/\sqrt{k_t}$ also being increased (k_p, k_t are the velocity coefficients for propagation and total bimolecular termination, respectively).

In our work, k_p/k_t was measured at 25° C by the rotating sector technique, with light of wave-length 3650 Å and azo-*bis*-isobutyronitrile as photosensitizer. The geometry of the sector was such that the dark periods had twice the duration of the light periods. Rates of polymerization were determined dilatometrically; it was shown that the relation between the contraction in volume and the extent of conversion is not changed by the presence of zinc chloride. In all cases less than 10 per cent of the incident light was absorbed.

The treatment of Matheson *et al.*[5], in which allowance is made for a finite rate of initiation in the dark, was used in evaluating k_p/k_t. (Note that we define k_t so that the rate of mutual destruction of radicals is $k_t[R\cdot]^2$, where $[R\cdot]$ is the radical concentration. Matheson *et al.*[5] write $2k_t[R\cdot]^2$ for the same quantity.) An approximate estimate of $R_p^s/(k_tI)^{\frac{1}{2}}$ was made by comparing plots of $\sqrt{3}.\bar{R}_p/R_p^s$ against $\log_{10}R_p^st_1$ with the appropriate theoretical curve. Values of $\log_{10}[R_p^s/(k_tI)^{\frac{1}{2}}]$ corresponding to each experimental point in the steeply sloping region of the curve were then found, and hence the mean value and the standard error of $\log_{10}[R_p^s/(k_tI)^{\frac{1}{2}}]$. ($R_p^s$, $\bar{R}_p$ are the rates of polymerization under constant illumination and intermittent illumination with the duration of a light period t_1, respectively.) Fig. 1 shows the plots obtained in the presence and absence of zinc chloride; clearly the salt changes the value of $R_p^s/(k_tI)^{\frac{1}{2}}$. The derived values of k_p/k_t in Table 1 indicate that the presence of the salt at a concentration of 1·42 mole l.$^{-1}$ increases the ratio by a factor of approximately 2·5.

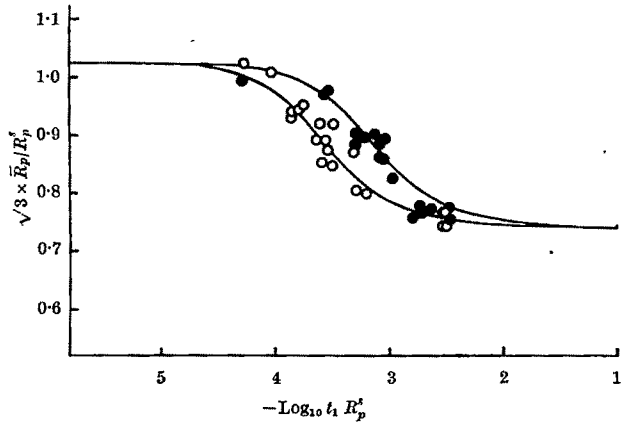

Fig. 1. Results obtained by the rotating sector technique. The ratio of the dark rate to R_p^s is 0·14. ○, Zinc chloride absent; ●, 1·42 mole l.$^{-1}$ zinc chloride

The magnitude of the ratio $k_p/\sqrt{k_t}$ (required to evaluate the rate coefficients separately) was obtained from molecular weight and rate determinations. Number average molecular weights were estimated from intrinsic viscosities. For this purpose allowance was made for the fact that termination occurs both by disproportionation and combination. If, with ordinary nomenclature, the relation:

$$[\eta] = K\bar{M}_n^a \qquad (1)$$

applies to a 'disproportionation' polymer, it may be shown that, if y is the ratio of combination to disproportionation:

$$[\eta] = K\bar{M}_n^a\left(\frac{2+y}{2(1+y)}\right)^a\left(\frac{1+y\,(1+\alpha/2)}{1+y}\right) \qquad (2)$$

Equation (2) was used to evaluate $\bar{M}_n$ from $[\eta]$, using the values of K, α given by Fox *et al.*[6], and taking $y = 0{\cdot}47$ at 25° C (Bevington *et al.*[7]). Finally, $k_p/\sqrt{k_t}$ was evaluated from equation (3).

$$\frac{k_p}{\sqrt{k_t}} = \frac{1}{[M]}\left(\bar{P}_nR_p\,\frac{2+y}{2(1+y)}\right)^{\frac{1}{2}} \qquad (3)$$

in which R_p is the rate of polymerization corresponding to a number average degree of polymerization $\bar{P}_n$.

Equations (2) and (3) are only valid if transfer is negligible. Imoto *et al.*[4], using the Mayo equation, derived a value of $2{\cdot}78 \times 10^{-3}$ for the transfer constant of zinc chloride at 60° C. However, the Mayo relation should not be applied to systems in which the rate of polymerization or the velocity coefficients are functions of the concentration of the transfer agent. A plot of the reciprocal of $\bar{P}_n$ (determined from equation (2)) against R_p at constant $[ZnCl_2]$ is linear and passes close to the origin, and is, therefore, consistent with the occurrence of only a very small amount of transfer. The transfer constant of zinc chloride must be less than 10^{-4} for $[ZnCl_2] = 1{\cdot}42$ mole l.$^{-1}$; use of equations (2) and (3) is therefore justifiable under our conditions. The degrees of polymerization were corrected to allow for transfer.

Table 1. Effect of Zinc Chloride on the Rate Coefficients in the Polymerization of Methyl Methacrylate at 25° C

Concentrations of the components of the reaction mixture, other than monomer, are shown. Photosensitizer azo-*bis*-isobutyronitrile (AZDN)

$[ZnCl_2]$ (mole l.$^{-1}$)	10^3[AZDN] (mole l.$^{-1}$)	$10^6k_p/k_t$	$k_p/\sqrt{k_t}$ (mole$^{-\frac{1}{2}}$ l$^{\frac{1}{2}}$ sec$^{-\frac{1}{2}}$)	$10^{-3}k_p$ (mole^{-1} l.sec^{-1})	$10^{-7}k_t$ (mole^{-1} l.sec^{-1})
0	1·89	10·6 ± 0·9	0·051 ± 0·001	2·5 ± 0·3	2·3 ± 0·6
0	6·10				
1·42	3·05	27·2 ± 3·0	0·128 ± 0·002	6·1 ± 1·0	2·2 ± 0·6
1·42	6·10				

The values of $k_p/\sqrt{k_t}$, and the individual values of k_p and k_t, are exhibited in Table 1. It is of interest that while k_p is increased markedly by zinc chloride, k_t remains virtually unaffected; in this respect the results resemble those obtained earlier with acrylonitrile and lithium chloride[1]. Our observations in the absence of zinc chloride are in good agreement with those of Matheson *et al.*[5].

The solution of zinc chloride in monomer has a high viscosity—about 73 per cent higher than that of pure methyl methacrylate (MMA) at 30° C. Imoto *et al.* showed from infra-red observations that the salt and monomer form a complex, which they formulated as $ZnCl_2$.MMA. It seemed likely to us that the complex might exist in polymeric form in solution, and thus give rise to the high viscosity. Measurements of the depression of the vapour pressure of the monomer are consistent with this and indicate a mean degree of association of 3·3. Probably some chains considerably longer than this are built up, with both zinc chloride and monomer acting as bifunctional units. Solutions of zinc chloride in ethyl acetate also show a similarly increased viscosity.

The marked increase in the velocity coefficient of chain propagation in the presence of zinc chloride could arise in several ways: (i) the salt might complex with the propagating radicals in such a way as to increase their reactivity to methyl methacrylate; (ii) the monomeric complex $ZnCl_2$.MMA may be more reactive than the monomer; (iii) chains of zinc chloride and MMA units may have the latter units arranged sterically in a manner suitable for polymerization.

Imoto *et al.*[4] carried out copolymerization experiments with vinylidene chloride at 20°–25° C., and, as these workers point out, their measurements of the reactivity ratio r_2 (vinylidene chloride is monomer 2) suggest that (ii) is important. However, the decrease in r_1 produced by the presence of the salt is larger than would be anticipated from our measurements of k_p alone; this may indicate complexing of the MMA radicals, which might well decrease k_{p12} in addition to increasing k_{p11}. (It is assumed in this argument that neither the vinylidene monomer nor radical is affected by zinc chloride.)

The constancy of the termination coefficient is consistent with the view that the high viscosity of the solution arises from the presence of a low concentration of polymeric chains.

Electron Spin Resonance Spectrum of $NH_2^+SO_3^-$

Changes in the electron spin resonance spectra of various carbon[1,2] and nitrogen[3,4] centred π-radicals on cooling to low temperatures prompted us to re-examine the spectra of the radical $NH_2^+SO_3^-$ trapped in irradiated sulphamic acid[5]. From the earlier work of Rowlands and Whiffen[5] it appears that at 300° K there is rapid re-orientation of the NH_2^+ group between two equivalent positions, so that the two protons are equivalent for all orientations of the radical in the magnetic field of the spectrometer. At 77° K a marked increase in the magnitude of the hyperfine interaction of the unpaired electron with the ^{14}N nucleus was noted for the orientation H_0 parallel to the crystallographic *b*-axis. It was suggested that this might be due to changes in the radical geometry.

In order to establish if this were indeed the case we examined the spectra at 4° K, at which temperature rotational motion no longer occurs. Furthermore, in order to improve the resolution of the spectral lines the radical has been generated in sulphamic acid enriched to over 95 per cent in the isotope ^{15}N. This material was purchased from Merck, Sharp and Dohme, Ltd., Montreal. Single crystals of sulphamic acid were grown from aqueous solution; they belong to an orthorhombic system[6] having $a = 8{\cdot}100$ Å, $b = 8{\cdot}049$ Å, and $c = 9{\cdot}228$ Å, and form hexagonal tablets on (100). Both X- and γ-irradiation facilities were used, at 300° K and at 77° K, in an attempt to minimize the formation of SO_3^-, the presence[7] of which partly obscures the spectra of $NH_2^+SO_3^-$. None of these experiments had any effect on the relative concentration of the two radicals. The electron spin resonance spectra were examined with a Varian V–4502 spectrometer previously described[4]. Room temperature data were obtained from a crystal mounted on a two-circle goniometer[8]; the low-temperature data were obtained from crystals mounted on quartz rods and immersed in Dewar vessels containing liquid nitrogen (77° K) or liquid helium[9] (4° K).

The proton and ^{15}N-hyperfine tensors determined from the spectra of $NH_2^+SO_3^-$ at 300° K are given in Table 1.

Table 1. Hyperfine Tensors for $NH_2^+SO_3^-$ in Sulphamic Acid at 300° K

Nucleus	Tensor* in *abc* axis-system (Mc/s)			Principal values	Principal directions
^{15}N	71·8	63·6	3·5	146·6	(+0·631, +0·727, +0·269)
	63·6	78·6	34·6	48·5	(−0·525, +0·146, +0 839)
	3·5	34·6	44·7	0·0	(+0·571, −0 671, +0 474)
Protons	64·1	−6·0	15·9	62·7	(+0·667, +0 715, +0·210)
	−6·0	71·7	−11·4	39·1	(−0·489, +0·207, +0·847)
	15·9	−11·4	51·1	85·1	(+0·562, −0·668, +0·488)

* These tensors refer to one particular site; the tensors for the other three sites are obtained by changing the signs of the off-diagonal elements in pairs, with appropriate sign changes in the fourth column. All four tensors have the same principal values.

The principal values agree well with those previously reported[5], when allowance is made for the different nuclear moments of ^{14}N and ^{15}N ($\gamma_{15}/\gamma_{14} = 1{\cdot}403$). Within the experimental error both tensors are diagonal in an axis-system defined as follows: perpendicular to the radical plane ($t_N = 147$ Mc/s, $t_H = 63$ Mc/s); parallel to the S–N bond ($t_N = 0$ Mc/s, $t_H = 85$ Mc/s) and the mutually perpendicular direction ($t_N = 48$ Mc/s, $t_H = 39$ Mc/s). From the crystal structure of sulphamic acid[6] it may be calculated that an S–N bond in the undamaged crystal has direction cosines (0·537, −0·743, 0·399) and that this vector makes an angle of $\cos^{-1}$ 0·993 or 6·9° with the largest principal value of the proton tensor. It is clear that at 300° K the radical $NH_2^+SO_3^-$ is a typical π-electron radical.

At 77° K the reorientation of the amino group had slowed to a frequency comparable with that of the hyperfine interaction, and consequently lines in the spectra arising from radicals the proton spins of which were antiparallel had broadened. Moreover, because of the anisotropic nature of the hyperfine interaction, this broadening was dependent on orientation. A complete analysis of the spectra at 77° K was not possible for this reason and, since our results add little to those of previous workers[5], no data are presented for 77° K.

At 4° K rotational motion of the amino group has ceased so far as the electron spin resonance experiment is concerned. All the lines in the spectra were sharp, and the two protons were distinguishable. As the magnetic field explored planes perpendicular to the orthorhombic axes two magnetically distinct sites, each giving rise to an eight-line spectrum, were apparent. Analysis of the spectra was made more difficult by the strong, and rather broad, signal from SO_3^-, and by the very small *g*-factor anisotropy in the spectra from $NH_2^+SO_3^-$ radicals. For these reasons no reliable estimate of the off-diagonal elements of the tensors can be offered. In Table 2 the observed hyperfine splittings of the three nuclei are listed for H_0 parallel to the three crystal axes. These splittings enable us to place an upper limit on the isotropic hyperfine interactions. The averages of the three diagonal elements listed in Table 2 are 109·5 Mc/s for the ^{15}N nucleus, and 64·6 and 66·6 Mc/s for the two protons. Since the off-diagonal elements of the ^{15}N tensor are not small, it is estimated that the isotropic hyperfine interaction cannot be greater than 95 Mc/s, or less than 75 Mc/s.

Table 2. Hyperfine Splitting of $NH_2^+SO_3^-$ in Sulphamic Acid at 4° K

Nucleus	Hyperfine splitting (Mc/s) with H_0 along axis		
	a	*b*	*c*
^{15}N	109·0	129·7	89·8
Proton	54·5	82·0	57·3
Proton	93·2	82·0	24·7

With regard to the possibility of a change in radical geometry at low temperatures, it will be recalled that the effect of changing the hybridization at the nitrogen atom from sp^2 to a non-planar configuration in which the hybrids used in bonding remain equivalent is to put *s* character into the orbital containing the unpaired electron. The fractional amount of such *s* character is $2\cot^2\theta$, where θ is the angle between the half-occupied orbital and one of the hybrids used in bonding[10]. Recently tabulated[11] *SCF-AO* data indicate a value for $\psi^2_{2s}(O)$ of 4·770 a.u. for nitrogen, and hence a hyperfine interaction of 2,161 Mc/s for an unpaired electron in an ^{15}N 2*s* orbital. It may be calculated that a distortion of 5° from planarity ($\theta = 85°$) would give a contribution to the isotropic ^{15}N hyperfine interaction of 33 Mc/s by this mechanism, and a distortion of 10° a contribution of 134 Mc/s. Such a contribution would add to that produced by spin polarization.

It is clear, however, that if the present estimate of 85 ± 10 Mc/s for the isotropic interaction at 4° K be accepted, a significant increase over that pertaining at 300° K (65 Mc/s) is apparent, and this may be due to a

distortion of ~5° from a planar skeleton at the nitrogen atom. On the other hand, an increase of comparable magnitude may well be due to the crystal field effects discussed by Rowlands and Whiffen[5].

We thank Dr. L. D. Calvert for determining the unit-cell directions in the crystals.

Equilibrium at the Solid–Liquid Interface

Ward and Brooks[1] in 1952 provided the only experimental justification for the much used assumption of concentration equilibrium at the interface during solid dissolution investigations. Using both Lamm scale and Rayleigh interferometer measurements of concentration gradients they calculated interfacial concentrations equal to the saturation values for the dissolution of salicylic acid and of *n*-butyl acetate in water. They also reported probable saturation for the benzoic acid–water system although the calculated concentration at the interface varied somewhat with the experimental method. It appears that a more appropriate instrument for such measurements would be the Mach–Zender interferometer, which permits the direct measurement of concentrations in the vicinity of a solid surface[2]. For the present work an interferometer was constructed similar to that described by Caldwell for diffusion studies[3]. The continuous light source was replaced, however, by a high-intensity, short-duration spark discharge[4] to provide better photographic resolution of the rapidly changing concentrations in the vicinity of the interface. This instrument was then used to investigate the dissolution in water of benzoic acid and of acetanilide.

The diffusion cells constructed for this investigation had two separate compartments arranged so that each was intersected by one of the interferometer light beams. The upper (reference) compartment was then filled with distilled water only, while the lower one contained both the solid under investigation and the water solution in which that solid was slowly dissolving. Powders of the appropriate solids were compressed into blocks in a hydraulic press under an applied pressure of approximately 10,000 lb./in.^{2}. The compressed solids were then carefully machined to fit into the cells and to provide flat, horizontal interfaces. Distilled water was permitted to fill the cell and overflow slowly. The water flow was then halted and a series of interferograms taken at convenient time intervals.

Fig. 1 is a typical set of interferograms. Parallel and vertical fringes on these photographs indicate a region of pure solvent. The number of fringes crossed while traversing downwards along a vertical path towards the interface gives the 'fringe shift' ($F.S.$) at any location. The concentration may be evaluated from the fringe shift at any point and the reference concentration as follows:

$$C - C_r = \frac{\lambda_0}{Lk}(F.S.)$$

a *b* *c* *d* *e* *f* *g*

Fig. 1. Interferograms for dissolution of benzoic acid in water. Time of contact: *a*, 2,340 sec; *b*, 2,820 sec; *c*, 3,360 sec; *d*, 4,020 sec; *e*, 5,040 sec; *f*, 5,820 sec; *g*, 6,300 sec

where λ_0 is the wave-length of the light beam in vacuum, L is the optical path length, and k is the concentration coefficient of refractive index. In this investigation the reference concentration, C_r, was always zero.

Interfacial concentrations were determined by measuring the maximum fringe shift from the undisturbed region to the interface by means of a Hilger microcomparator. Table 1 lists typical interfacial concentrations as well as saturation concentrations and calculated interfacial fluxes for both systems. The fluxes were obtained from the time-dependent concentration profiles measured for each system.

Table 1. Interfacial Concentrations at 25·25° C

System	Measured interfacial concentration (g/l.)	Measured saturation concentration (g/l.)	Interfacial flux (g/cm^2-sec)
Benzoic acid–water	3·273	3·370	$1·9 \times 10^{-7}$
Acetanilide–water	6·366	6·390	$1·83 \times 10^{-7}$

Because the observed interfacial concentrations are slightly less than the saturation values, it should be noted that the measured concentrations are distance averaged values along the optical path. Although care is taken to make the solid surface parallel to the interferometer beam, the camera cannot detect depression of the far side of the solid. The effect of any such surface misalignment or irregularity will be to reduce the apparent interfacial concentration by a slight amount. Thus, the measured deviations from equilibrium must represent a maximum value for this quantity with the possibility that the true deviation is somewhat smaller.

An interfacial transfer coefficient, β, was evaluated in the manner proposed by Drickamer[5]:

$$\text{flux}, J = \beta (C_{satn} - C_i)$$

For the conditions in Table 1, β assumes a value of $1·93 \times 10^{-3}$ cm/sec for benzoic acid in water and $7·51 \times 10^{-3}$ cm/sec for acetanilide in water. Since these parameters are nearly a thousand times greater than the respective diffusion coefficients, they far exceed the limits set by Drickamer for no measurable effect at the interface. Thus it is unlikely that a measurement of net mass flux between phases would detect any interfacial effect for either system, even if the departure from equilibrium reported for benzoic acid is realistic.

Relationship between the Number of Interacting Particles and Flux Ratio

When the flux ratio does not obey the Ussing relationship[1] in a passive system, interaction must be occurring between molecules of substrate passing through the membrane. By using a thermodynamic argument based on induced transport[2] it is possible to relate the deviation from the Ussing relationship to the minimum number of particles that interact without reference to the mechanism involved.

Consider two chambers I and II separated by a passive membrane. Suppose that the concentration of the substrate in question is C_I in chamber I and C_{II} in chamber II, and that there is a net flux of substrate from I to II. Let a very small quantity of radioactive substrate be added to the chambers. As diffusion of the substrate through the membrane occurs, suppose that there is a device that selectively removes the non-radioactive molecules of substrate from one chamber and returns them to the other so that the concentrations C_I and C_{II} are maintained unchanged. As a consequence of this process the radioactive molecules will eventually become distributed in such a manner that the flux of radioactive molecules in the two directions are equal, or:

$$k_I\, m_{I\to II} = k_{II}\, m_{II\to I} \qquad (1)$$

where k_I is the specific activity of the substrate in chamber I, k_{II} is the specific activity of the substrate in chamber II, $m_{I\to II}$ is the flux of substrate from chamber I to II, and $m_{II\to I}$ is the flux of substrate from chamber II to I.

As equilibrium is approached the free energy required to transport $\Delta m'$ moles of radioactive substrate from chamber I to II becomes:

$$\left(RT \ln \frac{f_{II}\, C_{II}\, k_{II}}{f_I\, C_I\, k_I} - z\,EF\right) \Delta m' \qquad (2)$$

where E is the electrical potential difference between chamber I and II (E positive if chamber I is positive), z is the number of positive electrical charges on one molecule of substrate, f_I is the activity coefficient of substrate in chamber I, f_{II} is the activity coefficient of substrate in chamber II, R is the gas constant and T is the absolute temperature. This expression is derived on the assumption that the energy associated with radioactive and non-radioactive molecules is the same, and from a consideration of the entropy changes based on the probabilities of the systems. The free energy made available when Δm moles of non-radioactive substrate pass from chamber I to II is, on the other hand:

$$\left(RT \ln \frac{f_I\, C_I}{f_{II}\, C_{II}} + z\,EF\right) \Delta m \qquad (3)$$

Since the energy to transport the radioactive substrate molecules must have come from the movement of non-radioactive substrate, it follows that if Δm molecules of non-radioactive substrate transport $\Delta m'$ molecules of radioactive substrate from chambers I to II:

$$\left(RT \ln \frac{f_I\, C_I}{f_{II}\, C_{II}} + zEF\right) \Delta m \geqslant \left(RT \ln \frac{f_{II}\, C_{II}\, k_{II}}{f_I\, C_I\, k_I} - zEF\right) \Delta m' \qquad (4)$$

Let $r = \dfrac{\Delta m + \Delta m'}{\Delta m'}$, then from equations (1) and (4):

$$\frac{m_{I\to II}}{m_{II\to I}} \leqslant \left(\frac{f_I\, C_I}{f_{II}\, C_{II}}\, e^{zEF/RT}\right)^r \qquad (5)$$

Consider the process involved in the interaction (for example, a polyvalent carrier or a long pore). If one radioactive substrate molecule takes part at any instant in the process it is probable that all the other substrate molecules at the same instant are non-radioactive since the radioactive molecules are present in extremely small concentration. Hence r must represent the number of molecules that, on average, interact. Consequently, if an equality is assumed in equation (5) the experimental value of r will give the minimum number of interacting particles.

It is possible for the interaction to be such that the radioactive substrate molecules are induced to travel in the opposite direction to the movement of non-radioactive molecules. In this case, equation (2) has a negative sign and if $\Delta m/\Delta m' = r'$:

$$\frac{m_{I\to II}}{m_{II\to I}} \geqslant \left(\frac{f_I\, C_I}{f_{II}\, C_{II}}\, e^{zEF/RT}\right)^{1-r'} \qquad (6)$$

r' is the average number of non-radioactive molecules associated with the movement of one radioactive molecule in the opposite direction. Again, if an equality is assumed in equation (6) the experimental value of r' will represent the minimum number of particles.

The flux ratio criterion may be applied to chemical reactions[3] and similar arguments may also be used concerning the number of interacting particles.

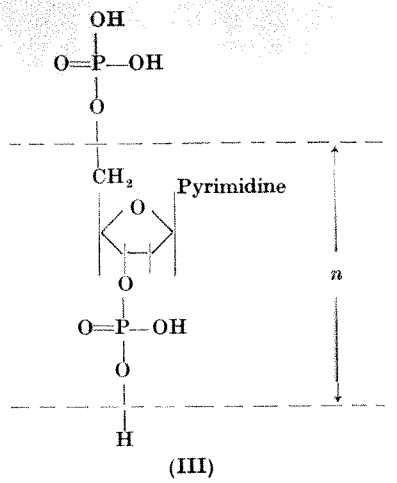
Use of Acidic Degradation for the Determination of the Distribution of Pyrimidine Nucleotides in Deoxyribonucleic Acids



Acidic degradation has been widely used to determine the distribution of the pyrimidine nucleotides in deoxyribonucleic acids (DNA; I). Two main methods have been used; in one the DNA was treated with 0·1 M sulphuric acid at 100° for 35 min, and in the other, 67 per cent formic acid and 2 per cent diphenylamine at 30° for 17 h were used[2]. In both procedures it appears that the first stage is the hydrolysis of the purine glycosidic linkages to give apurinic acid (II).

X is purine or pyrimidine residue

(I) (II)

It is claimed by the authors of the two methods that the next stage is the degradation of the apurinic acid to give products with the structure $(\text{pyrimidine nucleoside})_n$ phosphate_{n+1} (III).

(III)

It is apparent, however, that the results obtained by these two methods are not the same, and also that there is greater degradation of the DNA by formic acid and diphenylamine than by 0·1 M sulphuric acid under the conditions used[3,4]. The question arises as to which, if either, procedure gives the correct result for the distribution of the pyrimidine nucleotide residues in DNA. As we were interested in applying these procedures to some oxidized deoxyribonucleic acids, we have made a detailed comparison of the two methods.

Highly polymerized calf-thymus DNA was treated with 0·1 M sulphuric acid at 100° for 35 min as described elsewhere[1]. The purines were removed from the hydrolysate by absorption on a column of 'Zeo-Karb 225' and the solution of pyrimidine oligonucleotides examined by paper chromatography in propan-2-ol–ammonia (sp. gr. 0·88)–water (70 : 6 : 30) for 18 h. Only very small amounts of free purines could be detected. The whole of the pyrimidine oligonucleotide-containing zones were eluted from the paper and analysed for purines. Only 1·3 per cent of the adenine and 1·8 per cent of the guanine of the original DNA remained in the oligonucleotide fraction. When calf-thymus DNA was treated with 67 per cent formic acid and 2 per cent diphenylamine at 37° for 18 h (the original authors used 30°; we found it more convenient to use 37°, which gave essentially the same degradation) and the products were examined as already outlined, the oligonucleotide fraction contained 0·7 per cent of the adenine and 1·8 per cent of the guanine of the original DNA.

These results showed that in both methods the purine glycosidic linkages were essentially completely hydrolysed.

A large-scale hydrolysis of DNA (320 mg) with 0·1 M sulphuric acid at 100° for 35 min was then carried out and the hydrolysate exhaustively dialysed against distilled water. It was found that 18·4 per cent of the phosphorus did not diffuse through the dialysis membrane and that the material that did not diffuse contained 1·15 moles of cytosine and 1·71 moles of thymine/4 g atoms phosphorus and negligible amounts of purines. On treatment of the material with pure prostatic phosphomonoesterase, 28·7 per cent of the phosphorus was converted into inorganic phosphate, showing that, on the assumption that each oligonucleotide chain carried two terminal phosphate groups, the material had an average chain-length of six nucleotide units (seven phosphate groups).

These results showed that only five bases per seven phosphate groups were present compared with the six bases required by structures of the type (pyrimidine nucleoside)$_n$ phosphate$_{n+1}$ (III). It appeared, therefore, that 2-deoxyribose units were present which were not glycosidically linked to purines or pyrimidines. That this was so was confirmed as follows.

(*a*) The non-diffusible material was treated with the Dische diphenylamine reagent[5] (the solutions were heated for 4 min instead of the 10 min given in ref. 5) when the typical blue colour given by 2-deoxyribose and purine deoxyribonucleosides was obtained. The amount of colour (after allowance had been made for the small amount produced from pyrimidine nucleosides) corresponded with the presence of 1·11 2-deoxyribose residues per seven phosphate groups.

(*b*) The non-diffusible material was treated with intestinal phosphatase (a mixture of phosphomonoesterase and phosphodiesterase) and the mixture examined by paper chromatography in butan-1-ol–ethanol–water (4 : 1 : 5) and the 2-deoxyribose-containing compounds detected by the use of a cysteine-sulphuric acid spray[6]. In addition to thymidine and deoxycytidine, a spot corresponding to 2-deoxyribose was detected.

(*c*) When the non-diffusible material was treated with 67 per cent formic acid and diphenylamine at 37°, the characteristic blue colour (which appears when DNA is treated with the reagent) was produced and 4·7 per cent of the total phosphorus was converted into inorganic phosphate.

It appeared, therefore, that the 'free' 2-deoxyribose units were randomly distributed in the oligonucleotide chains because, if they were all end groups, the liberation of inorganic phosphate would have been about 14 per cent and if they were all single residues within the chain there would have been no inorganic phosphate.

The diffusible material was then examined by paper chromatography and found to contain a small amount (< 1 per cent) of thymidylic acid and deoxycytidylic acid. A small amount of thymine (< 1 per cent) and an appreciable amount of cytosine (5·5 per cent of the cytosine of the DNA) were also present. Small amounts of ultra-violet-absorbing components, which in the propan-2-ol–ammonia–water solvent had R_F values between those of thymidylic acid and thymidine-3′,5′-diphosphate, were also detected. These were not identified, but their spectra indicated that they probably contained pyrimidines. The treatment of the DNA with the 0·1 M sulphuric acid converted 13·1 per cent of the phosphorus into inorganic phosphate.

A similar investigation was then made of the action on DNA of 67 per cent formic acid and 2 per cent diphenylamine at 37° for 18 h. In this case only 10·1 per cent of the phosphorus of the DNA did not diffuse through the dialysis membrane and the non-diffusible material contained 1·38 moles of cytosine and 2·18 moles of thymine/4 g atoms phosphorus. The average chain-length was 6·7 phosphate groups. This showed that in this case no 2-deoxyribose residues were present which were not glycosidically bound to pyrimidines. This was confirmed by the fact that the material gave no reaction for 2-deoxyribose with the Dische diphenylamine reagent; moreover, after treatment with intestinal phosphatase, thymidine and deoxycytidine could be detected but no 2-deoxyribose.

The diffusible material contained a small amount (< 1 per cent) of thymidylic acid and deoxycytidylic acid, no thymine was present and the amount of cytosine present was only 1·2 per cent of the total present in the DNA. There were no ultra-violet-absorbing components running between thymidylic acid and thymidine-3′,5′-diphosphate on the propan-2-ol–water–ammonia chromatograms. The amount of inorganic phosphate produced during the reaction with formic acid and diphenylamine was 28·3 per cent.

These results show that treatment with 0·1 M sulphuric acid at 100° for 35 min does not completely degrade DNA to pyrimidine sequences of the type (pyrimidine nucleoside)$_n$ phosphate$_{n+1}$ (III), whereas with 67 per cent formic acid and 2 per cent diphenylamine at 37° for 18 h it appears that the degradation to (III) is essentially complete and specific. This explains why, in the former procedure, a greater amount of the longer nucleotide sequences was apparently present than with the latter. The degradation of these higher sequences (produced by

the action of 0·1 M sulphuric acid by a subsequent treatment with formic acid and diphenylamine) is therefore a specific degradation and not non-specific as has been claimed[4]. (It should be noted that a sequence of the type (pyrimidine nucleoside)$_n$ phosphate$_{n+1}$ cannot be degraded to two shorter sequences of the same type without liberation of a pyrimidine base or pyrimidine nucleoside.) Furthermore, the treatment with 0·1 M sulphuric acid liberated a considerable amount of cytosine. This may explain why sequences of four or more cytosine units were not found using this method, but were found when the other method was used[3]. This formation of cytosine also indicated that it was unlikely that the procedure could be improved by increasing the time or temperature of the reaction.

It can be concluded, therefore, that the method of choice for the determination of pyrimidine nucleotide distribution in DNA is the use of formic acid and diphenylamine; the results obtained here confirm those of the original authors and show that the method is highly specific.

BIOPHYSICS

Possible Mechanism of Thrombus Formation

It has often been observed that after trauma (and possibly under other conditions) the thrombi which form in the vascular system consist of a small white head (the white embolus) and a longer red tail[1]. The predominant constituent of the embolus is generally aggregated platelets, and some recent experiments may throw light on the mechanism of formation of the red tail, which consists primarily of red cells.

It is well known that when a suspension of rigid, neutral-density particles flows down a tube the mean velocity of the particles is slightly greater than that of the transporting liquid[2]. Thus when a suspension is first drawn through an empty tube there is an increase in the concentration of particles at the leading interface as it moves along the tube[3]. Blood behaves in a similar way to a suspension of particles in this respect[4], red cells congregating at the leading interface. Moreover, lower transit times (corresponding to higher velocities) have been measured *in vivo* for red cells than for plasma[5].

We have now been able to show that if, into a suspension of rigid particles flowing down a tube, a sphere is introduced the diameter of which is very near to that of the tube the concentration of particles immediately behind it increases, while that immediately ahead falls. Fig. 1 shows the result of introducing a polystyrene sphere of diameter 1·8 mm into a tube of diameter 1·9 mm down which a neutral-density suspension of polystyrene spheres, 0·35–0·42 mm in diameter, is flowing at a mean volume concentration of 5 per cent.

The reason for the concentration changes is that the wall exclusion effect which is the primary cause of the difference in mean velocity between the particles and the liquid is only important over a limited range of particle/tube diameters. It disappears when the particles are very small (that is, less than about 1/30th of the tube diameter)[3] and also when the diameters of the particles and the tube approach equality. The particle sizes for the experiment are chosen so that the small spheres try and overtake the large sphere but are unable to squeeze by it so that their concentration rises immediately behind the sphere and falls immediately ahead of it.

From the observed similarities in the flow behaviour of neutral-density spheres in a liquid and red cells in plasma which was mentioned earlier, there are good grounds for expecting that the concentration changes observed in a suspension adjacent to a close-fitting sphere in a tube would be paralleled by changes in the distribution of red cells near white emboli moving in vessels of appropriate diameters. The differential flow velocity of red cells and plasma should reach a maximum in the range of diameter of human blood vessels of about 15–50μ, so that vessels of this size would be most affected. Vascular occlusion would be most likely in vessels possessing a minimum of branches, and the chances of complete stasis would increase with decreasing elasticity of the vessel wall. The plug would be identified by a reduced concentration of red cells in the plasma immediately ahead of it and by a white head which practically filled the lumen. It would be interesting to discover whether occlusions of this type have, in fact, been observed.

The experiments described were made in the course of an investigation which is being financed by the Nuffield Foundation, which I thank for its support and encouragement.

BIOCHEMISTRY

Separation of Urinary Isoamylases on Cellulose Acetate

A number of electrophoretic investigations have been carried out on human α-amylases (*E.C.* 3.2.1.1.). Paper[1,2], agar[3,4], and polyacrylamide gel[5] have been used as media.

Fig. 1

Fig. 1. Electrophoresis of (*A*) pancreatic extract; (*B*) urine (normal) concentrated twenty times; (*C*) saliva

Norby[4] achieved separation of salivary and pancreatic isoamylases from extracts of their tissue of origin on agar gel and also showed that salivary amylolytic activity is itself complex—a point confirmed by Muus and Vnenchak[5] recently.

The present investigation on urinary amylases made use of cellulose acetate with veronal buffer as the separating system. The substrate, instead of starch-containing agar used by previous investigators[3,4], was a brand of hydrolysed starch of the type used for starch-gel electrophoresis[6] (Starch-hydrolysed Lot 227–1, Connaught Medical Research Laboratories, Toronto, Canada). This starch, made up with buffer in the concentration recommended by the manufacturer, provided an all-starch substrate of sufficient consistency to be cast by thin-layer chromatography apparatus on glass plates. Such a substrate has an advantage over those with an agar base because agar is not digested by α-amylases. The buffer was Michaelis[7] barbital sodium-acetate containing 0·02 M calcium chloride to prevent phosphorolytic digestion of the starch.

Twenty-two specimens of urine were obtained from healthy staff members of this hospital and three urine specimens from infants attending a well-baby clinic. The urines were filtered and concentrated twenty times by ultrafiltration. Extracts were made of salivary glands and pancreatic tissues from post-mortem subjects in the above-mentioned buffer. Diluted saliva was centrifuged to clear its mucin. Suitable dilutions were then made of saliva, salivary gland and pancreatic extracts. The amount applied to the strips was 1 μl. of each of the materials investigated. Electrophoresis was carried out at 0·4 m.amp/cm. width at 200 V for 1 h. The resulting strips were carefully laid on the starch-plates and incubated at 37° C. At the end of 30 min the strips were removed and the plates stained in 0·02 N iodine. The presence of amylolytic activity was revealed by clear areas against a purple background of undigested starch. All the bands of amylolytic activity were on the cathodic side of the origin. The result of one experiment is shown in Fig. 1.

The urine was observed to contain two isoamylases as revealed by their digestion of starch gel. The faster-moving component appeared to be the same as that obtained from saliva and salivary gland extracts. Extracts of pancreatic tissue produced a band with the same mobility as the slower band of the urine. The relative mobilities are similar to those revealed by agar-gel electrophoresis[4]. In another experiment the two bands of activity from urine and the single bands from saliva and pancreas were cut from the electrophoresis strip using portions of the same strips which have been developed on starch plates as markers. The isoamylases were eluted out with buffer, concentrated and re-run on cellulose acetate using *tris*-EDTA-borate buffer of Aronsson and Grönwall[8]. The relative positions of the bands were retained. The amylases of saliva and those present in extracts of sub-lingual, sub-mandibular and parotid glands appear to have the same electrophoretic mobilities. Two patients with symptoms and signs of pancreatitis had serum amylase levels of 2,200 and 320 Somogyi units per 100 ml. respectively. Their urines did not require concentration and were electrophoresed alongside concentrated normal urine. In both cases a distinct band of activity with a mobility similar to that of the pancreatic enzyme was seen (Fig. 2). The salivary band predominated in the urine from a patient with mumps.

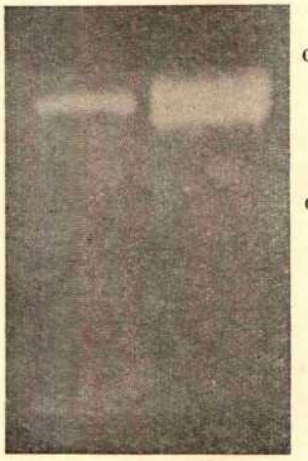

Fig. 2. Electrophoresis of (*P*) patient's urine; (*N*) normal urine concentrated twenty times. Note the absence of salivary amylolytic activity in the patient's urine which was not concentrated by ultrafiltration

The twenty-two adult urines yielded two bands each. Where they appeared well developed they were of equal intensity. This may not be surprising when it is noted that the weights of salivary glands and pancreas are roughly equal. The former apparently make a greater contribution to urinary amylase than previously suspected. Furthermore, in the urine of the babies investigated (all less than 1 year old) the band of pancreatic activity was significantly less marked than that associated with salivary amylase. According to Somogyi[9], plasma amylase, absent in the new-born, only reaches normal level in about 1 year. Pancreatic secretion of amylase is not well established in the first year of life[10].

The isoamylases of salivary glands and pancreas appear to be associated with definite proteins (Fig. 3).

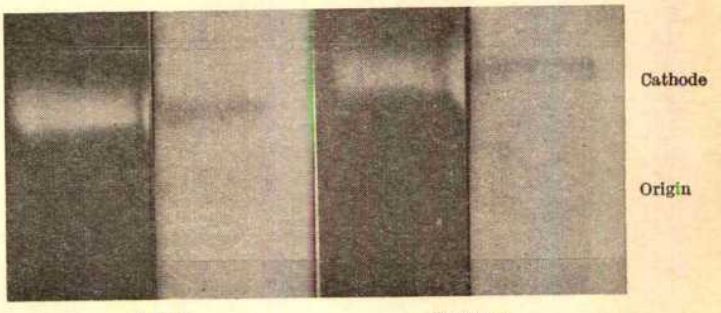

Fig. 3. Amylolytic activity of diluted saliva and pancreatic extract are shown alongside electropherograms of their sources. Protein stained with amidoschwarz 10*B* on the right, developed starch-plates on the left

Cellulose acetate electrophoresis of a urinary concentrate may prove of value in elucidating the nature of abnormal levels of serum amylases.

Fructose as a Component of the Foetal Blood and Foetal Fluids of the Bush Baby (*Galago senegalensis senegalensis*)

The presence of fructose in substantial concentrations in the foetal blood and fluids appears to be associated with those animals (ungulates and Cetacea) which have either an epitheliochorial or a syndesmochorial type of placenta[1]. The galago, although a member of the Primate Order, has a placenta of the epitheliochorial type[2,3] and is in contrast to many other members of this Order which have placentae of the haemochorial type. On the foregoing generalization, the placenta of *Galago* could be expected to produce fructose.

Three animals which had been mated in captivity at the Royal Veterinary College were anaesthetized intramuscularly with 2 mg/kg body-weight of 'Sernyl' (Parke, Davis and Co.) followed by inhalation of ether. Each animal bore a single foetus which was exposed by Caesarian section; at the same time samples of the foetal fluids were removed. Blood samples were obtained from both foetus and mother by cardiac puncture. The mating dates of the animals were not known. However, the foetuses were covered with a well-developed pelage, and from consideration of their crown-rump lengths and body weights it would appear that they were within a few weeks of the reported 4 months' gestation period[4,5].

All samples were deproteinized with barium hydroxide–zinc sulphate and the filtrates estimated for glucose and fructose by the glucose oxidase[6] and resorcinol[7] methods respectively. The resulting colours were read on a Spekker absorptiometer with a blue (Kodak No. 1) filter. The glycogen concentration in the placenta and foetal liver was estimated by a modification of Pflüger's method[8]. The values obtained in these determinations are shown in Table 1.

It will be seen that the glucose concentration of the maternal blood exceeded that of the foetal blood. Both foetal fluids had relatively low concentrations of glucose and in this respect they resemble the foetal fluids of the sheep[9]. Considerably more glycogen was present in the foetal liver than in the placenta. The fructose concentration of the foetal blood and in particular that of the foetal fluids is high. It was, however, observed that the resulting colour after heating with acid-resorcinol was atypical and indicated the presence of an interfering substance. It thus became important to establish the presence of fructose by other methods. The absorption spectrum of the acid-resorcinol colour produced by amniotic fluid was similar to that of a fructose solution in having peaks at 410 and 480 mμ when read in a Unicam *SP* 600 spectrophotometer. The slower decline of the amniotic fluid curve at the higher wave-lengths suggested that a substance having a broad absorption in the green region of the spectrum was superimposed on the curve. An attempt to reveal the absorption of this substance by the removal of fructose in an initial alkaline hydrolysis[10] proved unsuccessful and the subsequent absorption spectrum was similar to that given by the acid-resorcinol reagents (Fig. 1).

Some of the deproteinized samples were treated with indolyl-3-acetic acid[11] and gave absorption spectra identical to that of fructose in having a single peak at 520 mμ; an example is shown in Fig. 2.

Further confirmation of the presence of fructose in the samples was afforded by descending paper chromatography using amyl alcohol–pyridine–water (4 : 3 : 2) and butanol–acetic acid–water (12 : 3 : 5); the substances were visualized by a silver nitrate method[12]. In each animal fructose was detected in the foetal blood and in the amniotic and allantoic fluids. An example of a chromatogram is seen in Fig. 3.

It would seem, therefore, that fructose is present in a high concentration in the foetal blood and foetal fluids of

Galago senegalensis senegalensis, although an accurate determination may have been prevented by the presence of an interfering substance. Fahmy, Huggett and Pryce (unpublished) have obtained some evidence of its occurrence in the foetus of *Lemur mongoz*, which, like the galago, has an epitheliochorial placenta. These observations would thus appear to strengthen further the postulation that fructose in foetal life may, in some way, be related to placental histology.

Liberation of Adenine from Deoxyribonucleic Acid by Hydrogen Peroxide

Recently[1], we have established a metabolic cycle producing virogens and mutagens, in which hydrogen peroxide performs a central function. It is assumed that these virogenic and mutagenic metabolites can act on nucleic acids in cells. We have now demonstrated that adenine is specifically liberated from deoxyribonucleic acid molecule by the action of hydrogen peroxide.

Deoxyribonucleic acid was prepared from calf thymus according to the method of Kay[2] and dissolved in 0·14 M sodium chloride + 0·014 M sodium citrate. A mixture consisting of 2 ml. of deoxyribonucleic acid (4 mg/ml.) + 1 ml. of 2 M hydrogen peroxide + 1 ml. of 0·2 M *tris* buffer (*p*H 7·5) was kept at 37° C for 48 h. The solution was spotted on a 'Toyo' No. 51 filter paper and developed with an isopropanol–12 N hydrochloric acid–water (170 : 41 : 39) solvent. Guide spots were also made with a standard solution containing adenine, guanine, cytosine and thymine. Exposure to ultra-violet light revealed that the solution treated with hydrogen peroxide produced a spot of R_F 0·37 corresponding to adenine. To confirm this finding, the spot was cut off, extracted with 0·1 N hydrochloric acid and the ultra-violet absorption of the extract was measured. The curve obtained corresponded to that of adenine, having a maximum at 260 mμ and a minimum at 239 mμ. The reaction mixture after treating with 0·5 M hydrogen peroxide was also subjected to chromatography with a butanol–acetic acid–water (5 : 2 : 3) solvent. Only one spot of R_F 0·75 appeared on the paper and the solution obtained by extracting this portion with 0·1 N hydrochloric acid gave an ultra-violet absorption curve corresponding to adenine.

The reaction mixture, on the other hand, was dialysed against water and hydrolysed with 6 N hydrochloric acid at 100° C. Chromatography was carried out using an isopropanol solvent as already mentioned. The results showed that, while most of the adenine and thymine remained in the deoxyribonucleic acid-digest, guanine and cytosine were almost completely decomposed by 0·5 M hydrogen peroxide.

The experiments, therefore, were then conducted with 0·1 M hydrogen peroxide. The reaction mixture was incubated at 37° C for 72 h and a portion of it subjected to chromatography with the isopropanol solvent. Only one spot corresponding to adenine was produced. The spot was extracted as already described and the absorption of the extract measured at 260 mμ. The phosphorus of organic form in the reaction mixture was also determined according to the method of Eto[3]. From these analyses it was calculated that 35 per cent of adenine in the deoxyribonucleic acid used was liberated in the free state.

Another portion of the reaction mixture was dialysed and hydrolysed with 6 N hydrochloric acid. Chromatography was performed with isopropanol solvent. Four spots with R_F values corresponding to adenine, guanine, cytosine and thymine were formed on the paper. Extracts were separately prepared from these spots with 0·1 N hydrochloric acid. Their absorption was then measured at 260, 250, 275 and 265 mμ respectively. The estimation of phosphorus was further made for the reaction mixture after dialysing. The degree of decomposition of four bases in deoxyribonucleic acid by 0·1 M hydrogen peroxide was calculated from the data obtained. The results are given in Table 1.

These experiments revealed that, although considerable portions of all bases remained in deoxyribonucleic acid treated with a diluted hydrogen peroxide, only part of the

Table 1. Decomposition of Bases in Deoxyribonucleic Acid by 0·1 M Hydrogen Peroxide

	Relative amounts of bases			
	Adenine	Guanine	Cytosine	Thymine
Before treatment	0·29	0·21	0·21	0·29
After treatment	0·19	0·07	0·10	0·16

adenine was liberated. Supplementary experiments disclosed, however, that the proportion of the remaining bases varied to a certain extent with the concentration of peroxide or time of reaction, and that a liberation of adenine deoxyribotide occurs sometimes under mild conditions.

In Yamafuji's cycle, it is shown that nitrite, hyponitrite, hydroxylamine and oxime inhibit cellular catalase, thus leading to an accumulation of hydrogen peroxide[4]. Omura, at our Institute (personal communication), found that adenine and guanine were liberated from deoxyribonucleic acid by the action of hydroxylamine. In addition, Watanabe (personal communication) proved that the mechanisms of the reaction of hyponitrite and glucosoxime with nucleic acid-components were different from those of nitrite and hydroxylamine. These results indicate that four kind of nitrogenous mutagens and peroxide specifically act on deoxyribonucleic acid. Our present investigations also suggest that in a very low concentration these metabolites may cause a sufficient denaturation of nucleic acid molecules in cells after a long period.

Possible Structural Similarity between Insulin and Glucagon

Insulin and glucagon are pancreatic protein hormones which produce opposing physiological effects, the former lowering and the latter raising the concentration of sugar in the blood. With the elucidation of the complete amino-acid sequences of insulin[1] and glucagon[2] it became possible to compare the two structures in the hope of finding some correlation or complementary features in their sequences. Heretofore such comparisons have not revealed striking similarities or parallels between the two primary structures. Indeed, there are only four dipeptides which the two proteins have in common. This communication points out a similarity between the two primary sequences which are seen in Fig. 1.

The two interchain disulphide bonds in insulin form an 85 membered ring—27 amino-acid residues. The glucagon chain has 87 atoms in the backbone structure—29 amino-acid residues. If the NH_2 terminus of glucagon, histidine, is placed next to the histidine in the *B* chain of the large insulin ring, in the manner seen in Fig. 2, an interesting result follows. As the glucagon chain (indicated by the dotted line in Fig. 2) is laid along the insulin ring it is seen that the next residue, serine, coincides with a serine residue in insulin. The remaining two serines in the large insulin ring are exactly matched by serines in glucagon. The remaining serine in glucagon is matched by a glutamic acid residue in insulin. There are two other matching points in the sequences when compared in this way—threonine and tyrosine—as seen in Fig. 2.

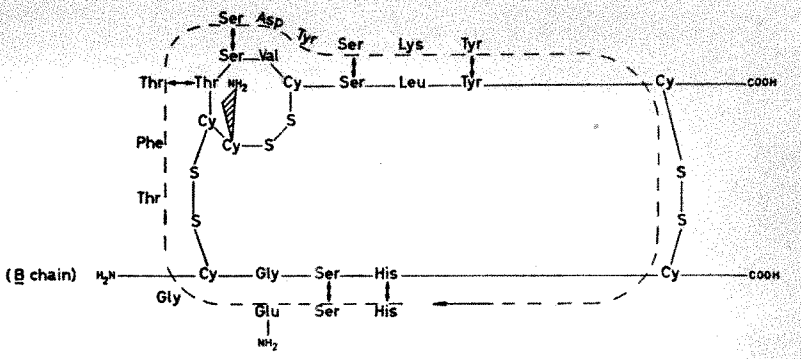

Fig. 2. Insulin is represented by the solid line and glucagon by the dotted line. The polypeptide chains are not drawn to scale. Distances between the amino-acids (with respect to histidine) are given in Table 1

In all, of the four hydroxl groups in the insulin ring, three are found to coincide with similar functional groups in glucagon. There are five amino side groups and two guanido side groups in glucagon, whereas the large insulin ring has one amino group.

A test of the closeness of fit of the large insulin ring and that proposed for glucagon shows good agreement. The difference in the total lengths of the two fully extended polypeptide chains is 3 Å, using the parameters of the fully extended trans-polypeptide chain[3]. The disulphide and sulphide bonds are relatively large, 2·04 Å and 1·82 Å respectively, and make up for the fewer number of peptide bonds in the insulin ring.

Table 1 summarizes the distances along the two fully extended chains. The correspondence is quite good in each case, showing that about one-fifth of all the amino-acids in glucagon have exact counterparts in insulin when the sequences are compared in this manner. There appears to be no sequential correlation according to hydrophobic or hydrophilic side-chains when the two rings are compared. However, it is true that the large insulin ring is richer than glucagon in the total number of hydrophobic side-chains, whereas the latter has more ionizable groups.

It is highly unlikely that either of these proteins exists in the fully extended conformation *in vivo* and yet there appears to be nothing in the structure of glucagon which would prevent it from assuming the conformation of the large insulin ring, whatever that may be. It is possible that the similarities between insulin and glucagon which are pointed out here are somehow related to the physiological action of these hormones and suggests that they may bind to a common site.

Two of the insulin residues involved in the correlation shown in Table 1 (threonine at 23·2 Å and serine at 26·9 Å) vary according to the animal source of the protein[5]. In beef insulin alanine is substituted for threonine, in horse insulin glycine is substituted for serine, and in sheep insulin both of these substitutions occur. Whether or not these differences

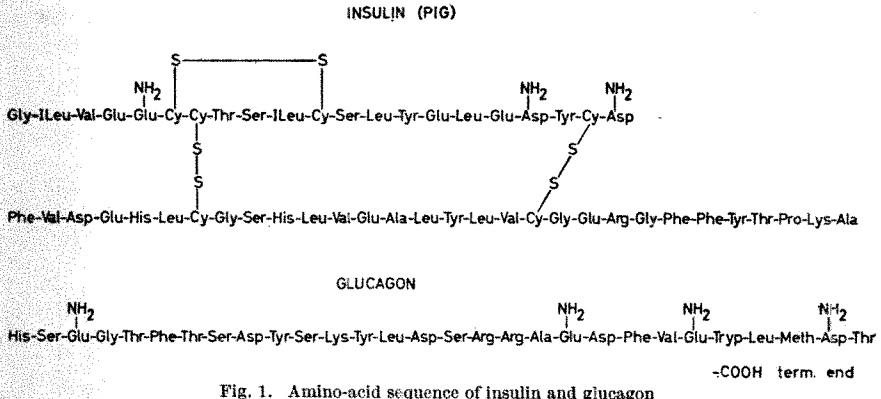

Fig. 1. Amino-acid sequence of insulin and glucagon

Table 1. Comparison of Distances between Amino-acid Residues when Insulin and Glucagon are aligned as in Fig. 2, in a Fully Extended Configuration

The distances are in angstroms and indicate the distances between α carbon atoms (refs. 3, 4)

Insulin (pig) Amino-acid	Distance (Å)	Glucagon Amino-acid	Distance (Å)
His	0	His	0
Ser	3·6	Ser	3·6
Thr	23·2	Thr	21·7
Ser	26·9	Ser	25·3
Ser	37·7	Ser	36·2
Tyr	45·0	Tyr	43·5

confer slightly different activities cannot be determined with current methods. Biological assays indicate that insulin from different animals has about the same activity[6].

One possible test of the significance of the correlations pointed out here would be to assay the activity of glucagon after it has been cyclized to form a new peptide bond across the ends. Such a reaction should be possible with current synthetic methods. If the foregoing similarity between insulin and glucagon is significant with respect to their mode of action then it is expected that the cyclized form of glucagon would be biologically active.

Effect of Age on Serum-bound Sialic Acid in Rats

Changes in the level of glycoproteins have been reported for a large number of conditions, primarily in man[1–6]. Since glycoproteins contain a number of sugar components for which quantitative methods are available, many of these methods have been used to estimate the serum- or plasma-bound carbohydrate. With the refinements of the thiobarbituric method[7] for a semi-specific assay of *N*-acetyl neuraminic acid, we have made use of this method to investigate the changes with age in the concentration of plasma-bound sialic acid in the rat in an initial effort to use experimental animals in the investigation of the physiological significance of glycoproteins.

Male Long–Evans Hooded Wistar rats were obtained from Simonsen Laboratories, Gilroy, California. After weaning, all animals were maintained on 'Purina' laboratory chow and water *ad libitum*. About 0·5–1 ml. of blood was obtained from the tail vein while the rats were under light ether anaesthesia. The blood was clotted and centrifuged and the serum was removed and stored at −40° C. Serum was diluted 1 : 50 and 1 : 30 in duplicates and hydrolysed in 0·05 N H_2SO_4 at 90° C for 30 min. *N*-acetyl neuraminic acid was determined by the Warren thiobarbituric method utilizing a known *N*-acetyl neuraminic acid preparation (an *N*-acetyl neuraminic acid of 95 per cent purity was obtained from Sigma Chemical Co., St. Louis, Missouri).

Data on the effect of age on serum-bound *N*-acetyl neuraminic acid are shown in Table 1. The results are

Table 1. Effect of Age on the Level of Bound *N*-Acetyl Neuraminic Acid in Serum

Age	No. of animals	Percentage of the 6-month value
22 days	10	28·8 ± 7·60
31 days	10	33·5 ± 8·28
55 days	9	96·5 ± 18·57
6 months	8	100 ± 33·02
14 months	9	162·9 ± 28·70

expressed as the percentage of the 6-month value. The 6-month value was 125·1 ± 41·3 mg of *N*-acetyl neuraminic acid per 100 ml. of serum in reference to the commercial preparation. These data clearly demonstrate that there is an increase in the concentration of the acid-labile serum *N*-acetyl neuraminic acid with age. The function or physiological significance of this elevation in the level of serum sialic acid and the chemical identity of the augmenting fractions is now being investigated.

Role of Lysosomes in Adrenal Necrosis caused by Dimethylbenzanthracene

It has long been recognized that carcinogenic chemicals, including polybenzenoid hydrocarbons, have injurious effects on cells[1,2]. Evidence has been presented that polybenzenoid hydrocarbons are concentrated in the lysosomes of living cells and the suggestion was made that release of lysosomal enzymes may play an important part in their cytotoxic action[3]. The necrosis of rat adrenal cortical cells produced by 7,12-dimethylbenz(*a*)anthracene (DMBA)[4] provided an opportunity to test this hypothesis in more detail, because it is specific in two ways. First, the degeneration is organ specific, adrenal cortical cells of the rat being much more sensitive than the cells of other organs. Secondly, it appears to be specifically produced by one compound, 7-hydroxymethyl-12-methylbenz(*a*)-anthracene (7-OHM-12-MBA), which is a metabolite of DMBA: an isomeric metabolite, 12-hydroxymethyl-7-methylbenz(*a*)anthracene (12-OHM-7-MBA), does not produce adrenal damage[5]. Rats can be protected against adrenal damage after administration of DMBA by previous treatment with a number of aromatic hydrocarbons and amines, which diminish the formation of 7-OHM-12-MBA from DMBA[5]. Hence it seems that the metabolite is more active than the parent compound in producing adrenal necrosis.

In order to ascertain whether there is any relationship between *in vivo* damage and release of lysosomal enzymes, particulate fractions of organelles from rat adrenals, kidneys and livers were prepared. In the case of the adrenal and kidney, the whole mitochondrial fraction, prepared by centrifugation of homogenates at 10,000*g* for 15 min, was used. The *F*3 fraction, a partially purified lysosomal preparation from rat liver, was used for comparison. This preparation, which was obtained by a sucrose layering technique, showed a twelve-fold increase in specific acid phosphatase activity as compared with the whole mitochondria preparation. The suspensions, adjusted by a standard turbidity (E_0 (500 mμ), 2·0) were incubated in 0·25 M sucrose buffered with 0·02 M *tris* pH 7·4. The carcinogen was dissolved in dimethyl sulphoxide (DMS) and added at the beginning of incubation. The

Table 1. Release of Acid Phosphatase from Particulate Fractions of Rat Adrenal, Kidney and Liver

	Conc. (μg/ml.)	Incubation time (min)	Percentage release of acid phosphatase Adrenal	Kidney	Liver
7-Hydroxymethyl-12-methyl-benzanthracene	100	15	23	—	5
7-Hydroxymethyl-12-methyl-benzanthracene	100	15	27	10	—
12-Hydroxymethyl-7-methyl-benzanthracene	100	15	7	—	—
DMBA	100	15	13	15	—
DMBA	100	30	22	—	6
DMBA	50	30	14	—	0
DMBA	10	15	9	7	—
Methylcholanthrene	100	15	5	0	—
Methylcholanthrene	10	15	2	0	—
Retinol	50	30	26	—	36
Control	—	15	2	3	—
Control	—	30	4	—	2

final DMS concentration was 2·5 per cent (v/v). At the end of the incubation period the preparation was centrifuged at 10,000*g* for 15 min and the free acid phosphatase estimated in the supernatant with *p*-nitrophenylphosphate as substrate. In some experiments retinol, a derivative of vitamin A known to increase permeability of lysosomal membranes[6], was used as a control. Other controls had the solvent alone. The percentage enzyme release is expressed as a fraction of that released by Triton X-100.

The results of several experiments, some of which are summarized in Table 1, show that retinol causes considerable release of enzyme from both adrenal and liver lysosomes, whereas 7-OH-12-MBA had a well-marked effect on adrenal lysosomes, but only a slight action on those of liver or kidney. 12-OH-7-MBA and 20-methylcholanthrene brought about no significant release of enzymes from either adrenal or kidney lysosomes. DMBA had some effect on adrenal lysosomes, especially after the longer incubation period shown in Table 1. The effect was, however, much less than that of 7-OH-12-MBA, and the possibility of metabolism of DMBA in this system has not been excluded.

It is clear that the membranes of lysosomes from different organs do not respond uniformly to the presence of chemicals. The membranes of rat adrenal lysosomes are highly sensitive to 7-OH-12-MBA, but less so to the isomer 12-OH-7-MBA, to DMBA, or to other hydrocarbons. Thus the *in vitro* results parallel the sensitivity *in vivo*, and it seems very likely that the adrenal necrosis observed in rats treated with DMBA is due to the concentration of 7-OH-12-MBA in adrenal cortical lysosomes with release of sufficient lytic enzymes to destroy the cells. There is other evidence that release of enzymes from lysosomes can irreparably damage cells[7].

The relationship of these results to carcinogenesis by DMBA and other hydrocarbons is not yet clear, but it has been suggested[3,7] that gradual release of enzymes from lysosomes over long periods may be implicated in malignant transformation. This process is likely to be different, quantitatively if not qualitatively, from the sudden and massive release of lysosomal enzymes which is probably involved in adrenal necrosis.

We thank Prof. E. Boyland and Dr. P. Sims for providing the metabolites of DMBA.

PHYSIOLOGY

Behaviour of Carbonic Anhydrase in the Uterus of Hens during Moult

The carbonic anhydrase present in the uterus of hens is involved in the calcification of the egg-shell[1]. The activity of this enzyme in the uterus seems to be greater in 'good' than in 'poor' layers or in non-layers[2]. Recently we pointed out that this enzyme is located at the apical pole of the cells of the tubular glands[3] (Fig. 1). We succeeded in demonstrating, by a histochemical method[4], that the reactivity of carbonic anhydrase is reduced in the uterus gland cells in moulting hens, whereas moulting has no influence on the carbonic anhydrase activity in the erythrocytes (Fig. 2). These results suggest an enzyme activation or an induction of enzyme synthesis similar to the effect of progesterone on the carbonic anhydrase in the endometrium of mammals[5,6].

In vitro Oxygen Consumption of Slices from Kidney, Brain, Cortex and Liver in Hypoxia

Most authors assert that the acute renal insufficiency observed in shock, or after haemorrhage, is due to the damage caused by hypoxia.

Munck's *in vivo* experiments showed that in haemorrhagic shock the oxygen saturation of renal cortex capillary and of renal venous blood was scarcely decreased. He therefore doubted the importance of hypoxia in his cases[1]. The degree of hypoxia is only one of the possible injurious factors; the other factor could be the sensitivity of different tissues to hypoxia.

In different mixtures of gases containing oxygen and nitrogen, we compared the *in vitro* oxygen consumption of renal cortex, brain cortex and liver slices.

White female rats (body-weight 130–150 g) were used. The animals were killed by decapitation. The rapidly removed organs were placed into Ringer phosphate buffer (*p*H 7·2; 0° C). The thickness of the slices was checked by Warburg's method. The respiration of 300 mg fresh wet tissue placed into 3 ml. buffer was measured in a Warburg apparatus. 0·1 ml. 20 per cent sodium hydroxide solution was used for absorbing carbon dioxide. Oxygen–nitrogen mixtures of different compositions were streamed through the flasks. Measurements were made at 30° and 37° C.

The oxygen consumption of renal cortex slices at 37° C was so strong that the deviation due to the frequent reading of the manometer was bigger than usual (see Tables 1 and 2).

Table 1. Oxygen Consumption of 300 mg Fresh Tissue/h, 30° C

	100% O_2	50% O_2	20% O_2	10% O_2
Kidney	476	416	254	164
$n = 12$	±37	±9	±43	±3
Liver	172	140	126	97
$n = 12$	±33	±4	±15	±10

Table 2. Oxygen Consumption of 300 mg Fresh Tissue/h, 30° C

	100% O_2	50% O_2	20% O_2	10% O_2
Kidney	442	323	247	148
$n = 16$	±45	±17	±13	±9
Brain	251	241	157	124
$n = 16$	±37	±11	±12	±9

Our experiments show that the oxygen consumption of the renal cortex is greatly influenced by hypoxia: (1) The oxygen consumption *in vitro* of renal cortex, brain cortex and liver slices is directly proportional to the logarithm of the oxygen content of the gas mixture (see Figs. 1–3). (2) The oxygen uptake of renal cortex slices decreased relatively more in gas mixtures with falling oxygen content than did that of the brain cortex and liver slices.

It can be assumed that the renal cortex is unable to take up the needed amount of oxygen even if the oxygen tension is relatively high. This means that a degree of hypoxia which is too small to damage other organs may produce severe alterations in the kidney.

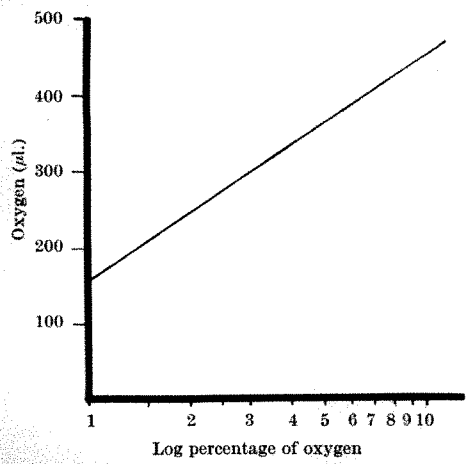

Fig. 1. Relationship between *in vitro* consumption of oxygen by the renal cortex slices and the log oxygen content of gas mixture. $y = 321{\cdot}9 = 293{\cdot}7\ (x - 1{\cdot}55)$

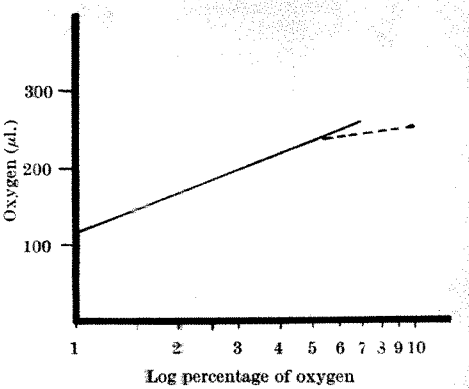

Fig. 2. Relationship between *in vitro* consumption of oxygen by brain cortex slices and the log oxygen content of gas mixture. $y = 175{\cdot}07 = 171{\cdot}4\ (x - 1{\cdot}34)$

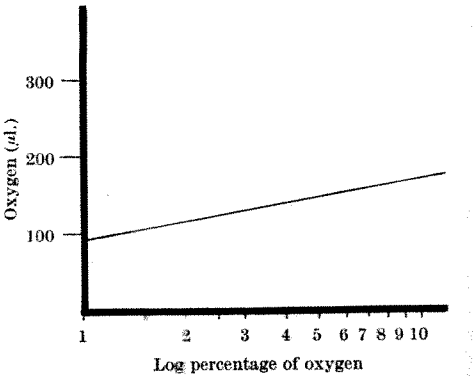

Fig. 3. Relationship between *in vitro* consumption of oxygen by liver slices and the log oxygen content of gas mixture. $y = 139{\cdot}2 = 79{\cdot}90\ (x - 1{\cdot}55)$

Time Course of Failure of Neuromuscular Transmission after Motor Nerve Section

After transection of a motor nerve, the severed part of the axon undergoes progressive changes known as Wallerian degeneration. But before the degenerating axon loses its ability to conduct action potentials, function and structure of the motor nerve terminals are impaired and neuromuscular transmission fails[1]. Several workers have noted that this failure occurs at a time which depends on the length of the degenerating nerve segment[2,3]. This communication describes experiments which make it possible to relate quantitatively the length of the degenerating axon to the time at which neuromuscular transmission fails.

The experiments were made on the phrenic nerve-diaphragm preparation of female albino rats (140–170 g). Operating under anaesthesia, the left phrenic nerve was sectioned, either near its emergence from the spinal cord in the neck, or in the thorax a few mm from the entry of the nerve into the diaphragm. In the former case, 3·5–4·0 cm of extramuscular nerve remained connected to the

diaphragm. At various times after nerve section, muscles were isolated and examined at room temperature (about 22° C) with intracellular microelectrodes to determine the functional state of the motor endplates. The endplates in the diaphragm are distributed within a band about 2 mm wide, the centre of which is about 1·5 mm toward the costal margin from the main intramuscular nerve trunk. In a normally innervated diaphragm spontaneous miniature endplate potentials (m.e.p.p.s) resulting from transmitter leakage from the nerve terminals are observed in more than 95 per cent of electrode penetrations made within this band. Failure to record m.e.p.p.s from this region of a muscle fibre is therefore a satisfactory indication that the discharge has ceased at that endplate. Endplates were sampled at 0·5 mm intervals following a course parallel to the intramuscular nerve trunk and making a total of 70–80 penetrations in most muscles. The presence or absence of m.e.p.p.s was recorded after each electrode penetration. Muscle fibres from which no spontaneous activity was recorded were examined for at least 1 min and many for longer periods. In those experiments in which the long length of nerve remained attached to the muscle, the nerve was stimulated to test whether transmission had failed at each junction.

The percentage of fibres examined at which m.e.p.p.s were observed (*a*) when the nerve was left long and (*b*) when it was cut short is plotted against the time after nerve section in Fig. 1. Each point summarizes the results from 150–200 impalements. The time course of the failure of transmission when the nerve was long was almost identical to that for the failure of m.e.p.p.s. In only a few instances were m.e.p.p.s recorded from muscle fibres which did not respond to nerve stimulation. In no case was transmission observed when m.e.p.p.s were not present. It is clear from these results that when the nerve had been cut far from the muscle, the failure of m.e.p.p. activity occurred about 3 h earlier than when the nerve had been cut close. It is also apparent that once the junctional failure started, it developed with a similar time course in both cases.

The results of Fig. 1 were further analysed to determine whether a varying length of the intramuscular nerve also influenced the time at which failure of m.e.p.p.s occurred. For this purpose, the observations were grouped, according to the distance of the endplate from the nerve entry, into four divisions each 0·5 cm wide. The results from each region were plotted as in Fig. 1, and the time at which m.e.p.p.s had failed at 50 per cent of the endplates ($t_{50\%}$) was read off the curve. These times have been plotted in Fig. 2 against the length of the sectioned nerve up to the mid-point of each region.

With the exception of the one point corresponding to the shortest length of nerve, there is a nearly linear relation between nerve length and $t_{50\%}$. The discrepancy in the region nearest the site of nerve section may be due to local acceleration of degenerative processes resulting from injury of the nerve at the nearby point of section. The regression line calculated for the remaining seven distances is given by $t_{50\%} = 0{\cdot}67\ L + 10{\cdot}4$, where L is the nerve length (cm) and $t_{50\%}$ is in hours.

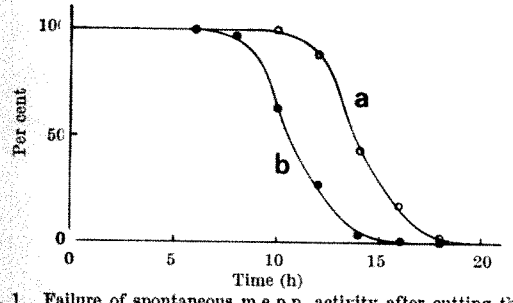

Fig. 1. Failure of spontaneous m.e.p.p. activity after cutting the rat phrenic nerve: (*a*) in the neck, 3·5–4·0 cm from the diaphragm (open circles); (*b*) in the thorax, 1–3 mm from the diaphragm (filled circles). Abscissa, time in hours after cutting the nerve; ordinate, percentage of impaled fibres at which spontaneous activity was observed. Pooled results from 1,500 penetrations in 23 muscles

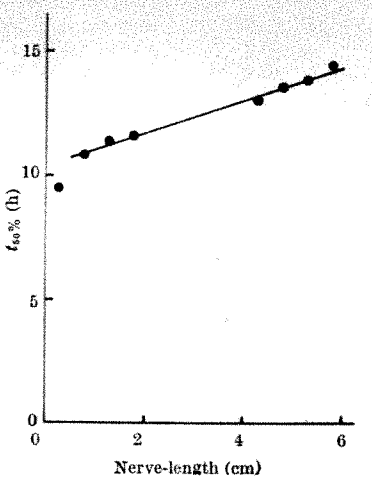

Fig. 2. Influence of the length of peripheral nerve stump on the time of m.e.p.p. failure. Abscissa, length of peripheral nerve stump in cm; ordinate, time at which m.e.p.p. activity has failed at 50 per cent of endplates

These results indicate that the presence of the peripheral nerve stump delays the failure of neuromuscular transmission after nerve section. For each cm of intra- or extra-muscular phrenic nerve remaining, the failure of m.e.p.p.s is delayed about 40 min. This is a smaller effect of the nerve than has been reported for peripheral nerve of the cat, where each cm adds about 5 h (ref. 3).

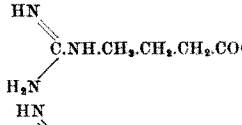
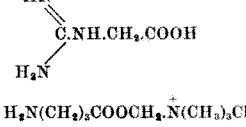
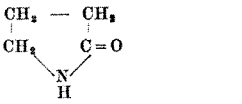
PHARMACOLOGY







Inhibition of *Ascaris* Muscle by γ-Aminobutyric Acid: a Possible New Assay Method

Ascaris lumbricoides, a round worm commonly found in the intestine of pig, has been used as an isolated muscle preparation for the investigation of anthelminthic potency[1]. We are now making a wider assessment of *Ascaris* as a pharmacological tool. Responses were recorded from a length of dorsal muscle, cut from the anterior region of the worm, mounted in an organ bath containing modified Tyrode's solution at 37° C (refs. 2 and 3). In our experiments the most striking pharmacological effects have been seen with γ-aminobutyric acid (GABA), which produced a rapid reversible inhibition of *Ascaris* muscle, reflected as a relaxation of the preparation, in concentrations as low as 0·5 μg/ml. The time required for full development of relaxation at this concentration is 3–4 min. In contrast, the common anthelminthic agent piperazine produces a much slower relaxation (more than 10–15 min) at concentrations of the order of 50 μg/ml. Similar relative concentrations of GABA and piperazine have been shown to depress spike potentials in *Ascaris* muscle[4,5].

The high potency of GABA suggested that its action might be structurally specific and this has been sub-

stantiated by the behaviour of some available congeners (Table 1). The spatial relationship of the amino and carboxyl group in GABA, and the primary character of the amino group, appear to be critical. The lactam, 2-pyrrolidone, for example, is inactive. The importance of the spatial relationship is particularly well illustrated by the high potency of guanidinoacetic acid. Alteration of chain-length and substitution of the amino or methylene groups markedly lowers activity.

Table 1. INHIBITION OF *Ascaris* MUSCLE BY GABA AND RELATED COMPOUNDS

Compound	Structure	Activity (GABA = 100)
γ-Aminobutyric acid	$H_2N.CH_2.CH_2.CH_2.COOH$	100
β-Aminopropionic acid	$H_2N.(CH_2)_2.COOH$	1·5
δ-Aminovaleric acid	$H_2N.(CH_2)_4.COOH$	9
ε-Aminocaproic acid	$H_2N.(CH_2)_5.COOH$	0·1
β-Aminobutyric acid	$H_2N.CH(CH_3).CH_2.COOH$	< 0·001
α-Aminobutyric acid	$H_2N.CH.COOH$ (C_2H_5)	< 0·001
Sodium butyrate	$CH_3.CH_2.CH_2.COONa$	< 0·001
Butylamine hydrochloride	$H_2N.CH_2.CH_2.CH_2.CH_3$, HCl	< 0·001
γ-Amino-β-hydroxybutyric acid	$H_2N.CH_2.CH(OH).CH_2.COOH$	< 0·001
Methylaminobutyric acid	$CH_3.NH.CH_2.CH_2.CH_2.COOH$	< 0·001
Glutamic acid	$H_2N.CH(COOH).CH_2.CH_2.COOH$	< 0·001
γ-Guanidinobutyric acid		7
Guanidinoacetic acid		43
γ-Aminobutyrylcholine chloride hydrochloride	$H_2N(CH_2)_3COOCH_2.\overset{+}{N}(CH_3)_3Cl^-.HCl$	2·5
2-Pyrrolidone		< 0·001

Ascaris is a convenient preparation for the assay of GABA. Concentrations between 0·5 and 2·0 μg/ml. give graded responses which lie on a linear regression line when plotted against the logarithm of the dose (Fig. 1). Results with other smooth muscle preparations have been described as variable[6,7]. The most satisfactory alternative involves inhibition of 5-hydroxytryptamine-induced contractions of the guinea-pig ileum, but this preparation, unlike *Ascaris*, is affected by many common endogenous substances. The usual method for assaying GABA, in which impulses are recorded from the crayfish stretch receptor neurone[8], is apparently reliable but technically more demanding.

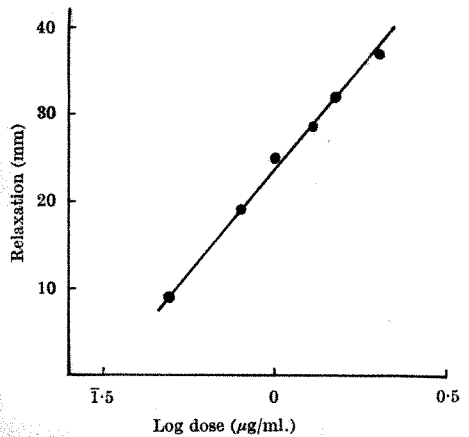


Fig. 1. Relaxation of isolated *Ascaris* muscle in modified Tyrode's solution by GABA. Doses were administered in random order at 7-min intervals

Ascaris is insensitive to many of the pharmacologically active substances present in brain, for example, noradrenaline, 3,4-dihydroxyphenylalanine, 3,4-dihydroxyphenylethylamine, 5-hydroxytryptamine and histamine in concentrations up to 2 mg/ml. Acetylcholine (0·2–2 μg/ml.), however, contracts the *Ascaris* preparation but the contractions may be blocked by *d*-tubocurarine[9] (20 μg/ml.); they are only slightly reduced by atropine (10–50 μg/ml.). We have not yet tested substance *P*, but on present evidence *Ascaris* appears to provide a simple and convenient means of studying the neuroanatomical distribution of GABA. The precision of the assay method is now under investigation.

GABA occurs in high concentrations not only in the central nervous system of vertebrates but also in the nervous tissue of some invertebrates[10]. Glutamic acid, the natural precursor of GABA, has been detected in *Ascaris*[11], but the possible occurrence or significance of GABA in *Ascaris* remains an open question.

HAEMATOLOGY

Effect of Basic Proteins on the Adhesiveness of Red Cells

THE methods already described[1,2] for measuring the stickiness of red cells to surfaces of various composition cannot be applied to the stickiness of red cells to each other ('adhesiveness' in the sense used by Conan[3]), for counting becomes difficult or impossible when neighbouring red cells form even small aggregates. Adhesiveness, however, can be measured in the following way.

A substance, for example histone, which increases the adhesiveness of red cells to each other, is dissolved in 1 per cent sodium chloride in a concentration of 2 mg/ml. Two ml. of this is diluted in a series of small tubes by powers of 2, and 0·5 ml. of a human red cell suspension in saline (50 mm³/10 ml. saline) is added to each tube. The contents of the tubes are allowed to sediment at 4° C, for 18 h. If the cells stick to each other, even in small clumps, they cover the bottom of the tube diffusely; if they do not stick to each other, they form a sharply defined 'button' at the foot of the tube. This effect is well known to serologists, and provides a very sharp end-point differentiating clumping (adhesiveness or stickiness of red cells to each other) from its absence. The end-point can be verified microscopically.

The effect of a second substance, for example albumin, on the adhesiveness produced by the first substance can be demonstrated by making serial dilutions in powers of 2 of the second substance (1 ml. of a concentration of 2 mg/ml., 1 mg/ml. . . .) and adding 1 ml. of the first substance in constant concentration (for example, 2 mg/ml.) and 0·5 ml. of red cell suspension to each tube. Readings

are made after 18 h at 4° C, using the same criteria as before.

The histone referred to below was prepared from calf thymus by acid extraction[4]; the salmine and lysozyme were pure preparations supplied by I.B.F. and N.B.C., respectively. All were dissolved in 1 per cent sodium chloride in concentrations of 2 mg/ml.; in this concentration the *p*H was between 6·7 and 6·9. The proteins keep in the refrigerator, but solutions must be freshly prepared. The other proteins referred to were purified samples, dissolved similarly.

Adhesiveness. The basic proteins histone and salmine produce increased stickiness of human red cells to each other, that is, increased adhesiveness, in concentrations greater than 0·015 ± 0·01 mg/ml. This effect is virtually irreversible by washing with saline, is unaccompanied by haemolysis in concentrations less than 2 mg/ml., and is almost independent of the red cell concentration in the system; this is probably because, as the concentration increases, the chances of contact between cells increases. These effects on adhesiveness are related to the effect of histone and salmine on the electrophoretic velocity of the red cells, which is rapidly reduced to zero in concentrations of the order of 1 mg/ml.

Lysozyme, in concentrations of 2 mg/ml. or less, has no effect on the adhesiveness of human red cells; in higher concentration it is haemolytic, and in much higher concentration (20 mg/ml.) it reduces the surface charge of human red cells[5].

Effect of fibrinogen and gelatine. The only plasma protein which affects the agglutinating effect of histone and salmine is fibrinogen, which, while not producing an increase in stickiness itself, increases red cell adhesiveness about eight-fold. Serum albumin and serum globulin have no effect in concentrations of 2 mg/ml. or less, although in much higher concentrations they form complexes with histone[5].

Gelatine in concentrations of 2 mg/ml. (at which level it decreases the stickiness of red cells to glass probably because it coats the glass—it is well known that it is not adsorbed on red cells) decreases the adhesiveness of human red cells to each other about four-fold in systems containing histone or salmine.

Haemoglobin O Arab in Sudanese

THE Northern and Southern Sudanese differ from an anthropological point of view. The first are primarily Arab, but with varying degrees of African mixture, while the second are Nilotic–Hamitic Africans. The latter can be divided into Northern and Southern Nilotes. Among some groups of Southern Nilotes, haemoglobin S is common[1,2], but it is absent or low in the Northern Nilotes, for example, Dinka, Shilluk and Nuer[3]. Occasionally, also, haemoglobin Stanleyville II is found which relates these populations to their southern and western neighbours[4,5]. In the Northern Sudanese, sickling is found at a low, but constant, rate in Khartoum (182 of 9,100 examined, that is, 2 per cent) and at a more variable rate in Western Sudan[6]. It seems that the Northern Sudanese possess haemoglobin O which relates them to their Arab neighbours. Indeed, haemoglobin O Arab was first reported in an Arab family in Israel[7], but it has recently been found also in Bulgaria[8].

In 1962, we reported the finding of haemoglobin O in a Northern Sudanese woman in Khartoum[9]. Over a 4-year period we have examined 9,300 unselected Northern Sudanese in Khartoum and have found eleven instances of the carrier trait for haemoglobin O Arab. The haemoglobin O was identified in all instances in the Sudan and in England by its electrophoretic (Fig. 1) and other properties[7] and characterized as O Arab in three instances, by examination of the peptides arising from tryptic digestion of the isolated abnormal haemoglobin fraction by fingerprinting[10] (Fig. 2).

The incidence of haemoglobin O Arab in Northern Sudanese is admittedly low (about 0·1 per cent), but when viewed in the light of other surveys numbering many thousands of persons in Africa, it assumed some significance. It is tempting to consider the haemoglobin to be an Arab feature, particularly since it was first found in an Arab family. However, one of the large-scale surveys which failed to reveal the presence of haemoglobin O Arab was conducted in Saudi Arabia[11]. It is thus possible that the haemoglobin O Arab of the Northern Sudanese may be part of their non-Arab heritage related to pre-simitic Egypt. It is worth recalling that sickling was also present in the Arab family in which haemoglobin O Arab was first described, and that sickling is not a feature of pure Arab ('Bedouin') stock, and that haemoglobin O Arab has recently been reported in three generations of an American Negro family[12]. Kantchev *et al.*[8] have suggested that haemoglobin O Arab in Bulgaria may be the outcome of an independent mutation. Before accepting this unreservedly, one has to consider carefully

the links between Bulgaria and various parts of the middle-east and north-east Africa provided by the movement of armies during the prolonged Turkish occupation of these regions.

Haemoglobin Typing of the Kerry Breed of Cattle

Two types of haemoglobin, designated Bov A and Bov B, have been identified in the blood of cattle by Bangham[1]. These are distinguished by their motility in paper electrophoresis; Bov A is the slow-moving and Bov B the fast-moving component. The type of haemoglobin which occurs in an animal is controlled by two simple allelic autosomal genes which give rise to three phenotypes A, AB and B.

In a survey of stud bulls in Britain, Bangham[2] found that with the exception of the Jersey, Guernsey and South Devon breeds all other British breeds exhibited A type haemoglobin exclusively, while in the case of Channel Island and South Devon bulls both B and AB types were encountered in addition to A type haemoglobin. In a subsequent survey of some cattle breeds of Europe and Africa, Bangham and Blumberg[2] found that B type haemoglobin occurred in breeds located geographically along a line running southwards through France into Africa, while cattle of north-east France, Holland and Denmark showed A type haemoglobin exclusively. This finding tended to support the suggestion of Boston[3] that one ancestral line of the Jersey breed originated in the Indus valley and permeated through Africa to Europe. The type of haemoglobin occurring in Kerry cattle—a breed native to Ireland—has not previously been reported and it was felt that haemoglobin typing might throw some light on the views of Moyles[4], who has suggested that the Kerry breed originated in mid-Asia.

The standards for the different types of haemoglobin were established according to the method of Bangham[1] using blood samples from different breeds, including Friesians, Shorthorns, Herefords, Guernseys and Jerseys, which exhibited the A, AB and B types. Blood samples were then collected from 25 Kerry cattle in a pure-bred Kerry herd and these were run on paper electrophoresis side by side with samples from other breeds. All twenty-five samples from the Kerry cattle contained the commonly occurring A type haemoglobin. This finding has more recently been confirmed by Dabczewski[5].

Haemoglobin typing, therefore, would suggest that the Kerry breed of cattle has no link with that ancestral line of Channel Island cattle but would appear to have an origin resembling that of other northern European breeds.

We thank Prof. F. St. G. Sleith for laboratory facilities.

IMMUNOLOGY

Active Immunization of Mice with Chagastoxin

Previously we reported on the immunology, immunochemistry and immunochemotherapy of experimental *Trypanosoma cruzi* infection in mice. *T. cruzi* has at least 9 antigens. Sonic lysates of the cultures contain antigens A, B, C, D, E, F, G and H, and the sediment contains B, E, D and X. Living trypanosomes have antigens B, E and G. Saline supernatant has antigens A, B and F, while distilled water supernatant has A, B and E, and sediment antigens B and X. The recently phenolized cultures have A, E, G and X, and old phenolized cultures have only B. 50 per cent extraction with ammonium sulphate yields A, B, E, G and F. 100 per cent saturation still extracts B, while precipitation with alcohol after full saturation with ammonium sulphate still extracts antigen B. The phenol extract and sediment (Westphal) contain no antigens, but phenol aqueous extract contains antigen B. The antigens B, E and G are major antigens. The agglutinin titre of hyperimmune rabbit serum was 1 : 10,240 and that of horse serum was 1 : 327,600. Both rabbit and horse hyperimmune sera had 1 : 4 titre of agar-gel precipitin. Immunotherapy with hyperimmune rabbit serum prolonged the survival time in fatal *T. cruzi* infection in mice two- to three-fold. Chemotherapy with 1-furaltadone, in doses of 50 mg/kg/day for two weeks, followed by 12·5 mg/kg/day for 2·5 months, protected 86·7 per cent of infected mice, while combined immunochemotherapy with hyperimmune rabbit serum plus 1-furaltadone protected all mice for at least 5 months[1–3].

The present report deals with the toxicity and immunizing properties of the lipopolysaccharide, chagastoxin.

Phenol extraction. Chagastoxin is prepared or extracted using the following modified Westphal method[4], used for the extraction of lipopolysaccharides from the cell walls of Gram-negative rods. *Trypanosoma cruzi* (Tulahuan) is grown for 10–12 days on brain heart blood agar (Difco), containing 5–8 per cent citrated human blood obtained from the blood bank, in Roux bottles. The cultures are pooled, should contain no bacteria and erythrocytes, and are sonically lysed for 90 sec in Raytheon sonic oscillator model *DF*01, 10 kc/s, 250 W, 115 V and 60 c/s. After spinning, the sediment and supernatant are treated with an equal volume of 88 per cent phenol for 30 min in the refrigerator. It is then centrifuged at 3,000–4,000 r.p.m., and the supernatant is then dialysed for 3 days in running tap water and for 24 h against distilled water. The sediment is precipitated with alcohol or is directly lyophilized. The phenol fraction is precipitated with 95 per cent alcohol (6–10 volumes); the sediment is washed in saline and then lyophilized. Gentle handling is

necessary, otherwise the phenol sediment may disperse in the aqueous or phenol phases.

Ammonium sulphate extraction. The lysed trypanosomes are centrifuged, and the supernatant is then treated with ammonium sulphate so that its final concentration is 50 per cent. When 54·2 g ammonium sulphate is added to 100 ml. distilled water, the resulting solution is fully saturated. For 100 per cent saturation, ammonium sulphate crystals are added until full saturation is reached. The precipitate, after full saturation, is then dialysed against tap water for three days, distilled water 24 h, and then lyophilized.

Sheep were immunized with formalin–phenol-killed *T. cruzi* culture, had an agglutinin titre of 1 : 20,280, but they had no agar-gel precipitin antibodies. The agglutinin titre of sheep immunized with ammonium sulphate extracts was 1 : 5,120, and they had no agar-gel precipitin antibodies.

Protective effect of chagastoxin. Formalin–phenol-killed cultures of *T. cruzi* have no protective effect. Freshly lysed virulent cultures have low or weak protective value. The quantity of antigenic material in lysed cultures is low, and a large volume of material cannot be injected into mice. 50 and 100 per cent ammonium sulphate extracts also have low or weak protective value. Old lysed cultures do not have protective value. The immunizing/protective factor is very unstable.

Forty-five mice weighing 8–10 g were injected intraperitoneally with 0·5 mg chagastoxin, twice a week, for seven doses. There were fifteen control mice, of the same age and weight. Two weeks after the last dose of toxin, all mice were challenged with 120 *M.L.D.* of *T. cruzi* from an infected mouse. *M.L.D.* of *T. cruzi* was about 1,000 trypanosomes from an infected mouse. The controls died in less than 7 days, while the immunized mice lived up to 40 days. Naturally, such heavy infection does not occur in persons who are exposed to triatomid bugs which are infected.

Toxicity of chagastoxin. According to the criteria of Milner *et al.*[5], the surface antigens or lipopolysaccharides of Gram-negative bacteria should fulfil the following requirements: lethal effect expressed in $L.D._{50}$, protective or immunizing properties, pyrogenicity in rabbits, Shwartzman reactions and skin tests. Freshly lysed virulent cultures, phenol–formalin-killed cultures, ammonium sulphate extracts, phenol extract and phenol sediment are all non-toxic to mice. Chagastoxin (lipopolysaccharide) as a phenol aqueous supernatant is toxic to mice. 2·5 mg injected intraperitoneally each day for three successive days, in mice weighing 10 g, or 5 mg daily for three days in mice weighing 25 g, killed 50 per cent of animals within less than a week. 1γ of chagastoxin injected intravenously in rabbits raised the temperature 2° in 2–3 h, and 10γ raised the temperature 6·8° F during 2 h, the temperature then falling gradually. 1 mg chagastoxin injected intradermally in clean rabbits failed to give rise to a dermal reaction, but the same amount injected in rabbits immunized with killed and live cultures gave rise to a positive dermal reaction.

At present we are actively investigating the problem of immunization, using various doses and durations, intervals between immunization and challenges with virulent trypanosomes, and varying the doses of the challenge. We are also investigating the effect of the booster dose of chagastoxin, the pharmacology and pathology of the toxin in animals, and the effect of chagastoxin in the therapy of chronic lesions in animals. It should be borne in mind that, in the chronic stages of the disease, there are few parasites in the cells or tissues. Probably most of the damage at cellular or tissue level could be the result of the Arthus phenomenon, through exposure of the host to the antigen to the parasite. Chagastoxin may play a part in desensitizing the tissues to further damage by the parasite, or it may increase the permeability of the cell membrane to 1-furaltadone, thus increasing the lethal action of the drug to the pathogen. At present immunochemotherapy in chronic Chagas disease in animals is being investigated, using chagastoxin plus 1-furaltadone.

Note added in proof. Since the submission of this paper to *Nature*, we would like to report the following important experimental observations: (1) Sixteen doses of 500 μg chagastoxin intraperitoneally in mice, and challenged four weeks later with one to two thousand virulent trypanosomes, completely protected the animals during 140 days of observation, whereas control mice died in 7–10 days. A booster dose of four doses of 250 μg chagastoxin prolonged the duration of protection in previously immunized animals. The height of protection was attained one month following immunization. (2) Smaller doses of 25–200 μg chagastoxin rendered partial protection. (3) Formalinized chagastoxin was less effective than freshly prepared suspension. (4) Chagastoxin had a cortisone-like effect. Three doses of 10–500 μg activated fatal trypanosomiasis in chronic latent trypanosome infection in mice, but smaller doses failed to activate acute infection in chronically infected animals. (5) Chagastoxin induced marked leucocytosis in rabbits.

PATHOLOGY

Long-term Culture of Lymph Node Tissue from a Patient with Lymphocytic Lymphoma

Attempts to grow normal lymphoid tissue for extended periods of time in a state of morphological and immunological differentiation have been met by failure[1,2]. An alternative procedure involves short-term incubation of lymph node or spleen cells from previously immunized donors[3–7]. A short time ago Ioachim[8] reported successful long-term cultures of normal splenic tissue with continuous production of plasma cells from several mammalian species, including man. Simultaneous attempts with lymph node explants were unrewarding. On the other hand, continuous *in vitro* growth of mouse lymphomatous cells has been repeatedly accomplished[9–11]. Recently, Epstein *et al.*[12] reported long-term cultivation of Burkitt lymphoma cells.

This communication refers to a unique cell line obtained after *in vitro* culture of lymph node tissue from a patient with a well-differentiated lymphocytic lymphoma. The growing population is characterized by cell heterogeneity and evidence of morphological and immunological differentiation.

The patient is a fifty-eight-year-old male who noted an enlarged lymph node behind his ear in August 1962. He came to the University of Texas M.D. Anderson Hospital and Tumor Institute in October 1964 with generalized lymph node enlargement, the largest node being 3 cm in diameter. The liver and spleen were palpable. White blood cell count at that time was 41,500 with 3 per cent neutrophils, 91 per cent lymphocytes, and 6 per cent immature lymphocytes. A cervical lymph node biopsy was diagnosed as lymphocytic nodular lymphoma. He was

treated with 'Leukeran' for about 2 weeks. The patient has remained relatively well until the present time and his most recent count was 104,000, 85 per cent of which were mature lymphocytes.

A portion of his initial lymph node biopsy was immediately incubated with 'Colcemide' for chromosomal analysis, and the rest placed in a sterile Petri dish partially filled with Hanks's solution. The tissue was finely minced and the small pieces were distributed under perforated 'Cellophane' membrane in *T*-30 flasks. Approximately 4–5 ml. of culture medium was added to each container. The culture medium in use in our laboratory is *F*-10 (Colorado Serum Co., 4950 York Street, Denver, Colorado) supplemented with 20 per cent foetal calf serum (Hyland Laboratories, 4501 Colorado Blvd., Los Angeles, California) and 'Neomycin', 0·1 mg per ml. The vessels were then incubated at 37° C, and the medium changed every 3 days.

Outgrowth of spindle cells from the margins of the small explants were noted 2 weeks later. From the beginning phase microscope observation revealed two different types of cells: one larger, partially elongated and occasionally flattened containing a central nucleus and abundant granular cytoplasm, and the other, smaller, round or ovoid in shape with a lesser amount of cytoplasm and often condensed nucleus (Fig. 1). Since these latter cells were initially considered to be remaining lymphocytes it was assumed that with periodic change of medium they would disappear. However, this did not occur. With routine sub-culture every new flask contained the two cell types.

The reticular cells differed from the usual fibroblastic growth obtained from cultures of human skin, leukaemic bone marrow, and normal lymph nodes. They attached to the glass surface and proliferated, forming an interlacing network with nest-like spaces occupied by clusters of round cells. The latter elements predominated in the supernatant and often were seen floating freely in the medium (Fig. 1). Multiple cytoplasmic budding was also observed in both cell types. After centrifugation of the medium used, the resultant pellet was successfully utilized to start new cultures, which disclosed similar growth patterns.

It is of interest to mention that similar symbiotic cultures of reticular and lymphocyte-like cells have been reported in other species by a few investigators[13,14]. In a recent work Ioachim and Furth[15] described a long-term culture of virus-induced thymic lymphoma of rats which grew in a manner very similar to ours. At present, 12 months after the initial explants, our cell line still retains the heterogeneous population described. A permanent stock of these cells has been stored at minus 70° C in 5 per cent glycerine medium. A few ampoules of this material have been re-used with good recovery.

Fig. 1. Phase-contrast microphotograph of a 12-month-old culture from lymph node tissue of a patient with lymphocytic lymphoma. Two cell types are clearly seen. (× *c.* 400)

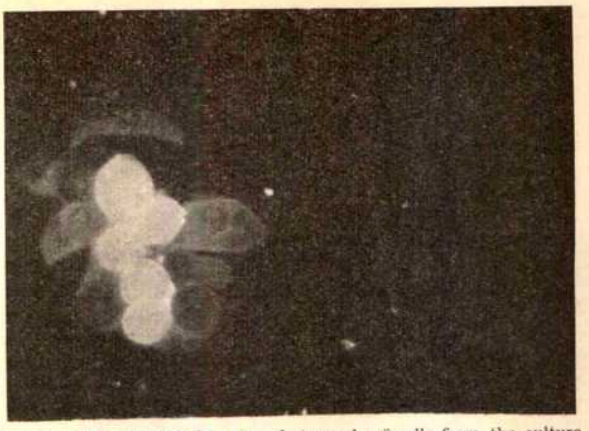

Fig. 2. Ultra-violet light microphotograph of cells from the culture shown in Fig. 1 after direct exposure to fluorescein-labelled rabbit anti-human gamma globulin serum. The round cells fluoresced strongly while the reticular elements remained unaffected. (× *c.* 400)

To investigate further the significance of this cell heterogeneity we used specific rabbit anti-human gamma globulin (Baltimore Biological Laboratories Division, 2201 Asquith Street, Baltimore, Maryland) labelled with fluorescein isothiocyanate (Calbiochem, 3625 Medford Street, Los Angeles, California). This was applied directly to the cultured cells and incubated for half an hour. Simultaneously, indirect techniques requiring previous exposure to unlabelled rabbit anti-serum were also carried out. Several normal and neoplastic human cell lines (fibroblasts, melanoma) were used as controls. With the direct technique the round cells revealed striking positive fluorescence (Fig. 2). The reticular cells were negative. Indirect techniques considerably reduced the fluorescence and the controls were consistently negative.

On the basis of these results it can be postulated that the two cell types observed under the phase microscope are functionally different: the spindle variety represents a reticular undifferentiated cell and the other, a more mature one, probably of lymphocytic origin. The fact that these round cells appear to be able to produce a protein molecule which can react specifically with the anti-human gamma globulin is most unique—especially considering the age of this cell line.

The initial chromosomal analysis showed euploidy, but subsequent periodical investigations indicated a change to aneuploidy around the sixth month. However, no evidence of a predominant mode has been found. More detailed cytogenetic data, as well as the results of histological, immunological, microcinematographic and other studies now in progress will be reported at a later date.

Aflatoxin: a Site of Action in the Rat Liver Cell

Aflatoxin is the name given to a group of related toxic agents produced by the mould *Aspergillus flavus* and which have been characterized chemically[1,2]. Diets containing aflatoxin, such as toxic ground-nut meal, have been found to produce pathological changes[3–6], in particular, liver injury[7], in a wide variety of species of animals. The most toxic member of the aflatoxin group so far recognized has been designated aflatoxin B_1 (ref. 8). The rat is considerably less susceptible to aflatoxin than most other species investigated and for male rats the LD_{50} is 7 mg aflatoxin B_1/kg body-weight (administered by stomach tube, dissolved in dimethylformamide 5 mg/ml.)[9]. Such a dose produces an extensive hepatic periportal necrosis after 48 h. It seems likely that the toxic agent has a direct action on the liver as within 30 min of administration it is possible to detect aflatoxin B_1 in the liver[10] and within 60 min most of the administered dose has been concentrated there.

We have found that by 1 h after poisoning slices cut from the liver of the poisoned rat have a reduced ability *in vitro* to incorporate radioactive amino-acids into the liver cell protein. Using radioactive labelled DL-leucine-1-^{14}C, L-alanine-^{14}C (U) or mixed amino-acids-^{14}C(U) prepared from a *Chlorella vulgaris* hydrolysate, percentage inhibitions after 1 h of incubation of 48, 44 and 24, respectively, were demonstrated by comparison with slices from control animals. Similarly the addition of a final concentration of 0·032 mM aflatoxin B_1 to the incubation medium containing liver slices prepared from control animals inhibits the incorporation of DL-leucine-1-^{14}C into liver proteins by 46 per cent after 1 h. Inhibition of protein synthesis in both animals and plants following the administration of aflatoxin B_1 or diets containing toxic groundnut meal has been previously reported[11–14].

To study further the effect of aflatoxin B_1 on protein synthesis *in vivo* the induction of tryptophan pyrrolase by substrate or cortisone was measured in the livers of control and aflatoxin B_1-treated rats. Three hours after poisoning it was found that there was a 57 per cent inhibition of the cortisone-induced enzyme whereas there was no inhibition of the substrate-induced enzyme. These findings are similar to those reported for the effect of actinomycin *D* on tryptophan pyrrolase induction[15–17].

It has been shown that the inhibition of protein synthesis in the liver of the rat following administration of actinomycin *D* is secondary to an inhibition in ribonucleic acid (RNA) synthesis[18]. To determine whether a similar sequence of events occurs with aflatoxin B_1, using liver slices from control rats we examined the effect of the addition *in vitro* of the toxic agent on the incorporation of ^{14}C-orotic acid into RNA and ^{14}C-leucine into protein. Table 1 presents results of such an experiment showing that there was an immediate inhibition of orotic acid incorporation into RNA whereas the inhibition of leucine into protein took some 15 min to develop. It was shown that aflatoxin B_1 does not inhibit the entry of amino-acids into the liver slice. These results thus indicate a similarity in action of aflatoxin B_1 to that of actinomycin *D*.

It was also possible to demonstrate an inhibition of the incorporation *in vivo* of ^{14}C-orotic acid into the RNA of the liver cell nucleus in rats poisoned with aflatoxin B_1. In Table 2 are given the results of a typical experiment and it may be seen that there is no inhibition of incorporation of orotic acid into the nucleotide pool but there is a marked inhibition of incorporation of nucleotide precursors into the nuclear RNA. This would seem to indicate that there is an inhibition of RNA polymerase—the only enzyme known to be operative between these two stages[19].

Table 1. *In vitro* Effect of Aflatoxin B_1 on the Incorporation of ^{14}C-Orotic Acid into the RNA and on ^{14}C-Leucine into the Protein of Liver Slices

Duration of experiment (min)	Per cent inhibition of incorporation in the presence of aflatoxin B_1 into RNA	Protein
15	92	5
30	88	31
45	95	43
60	90	46

Liver slices were prepared from control rats and incubated in Krebs–Ringer phosphate, with oxygen as gas phase. 1 μc. of orotic acid-6-^{14}C or DL-leucine-1-^{14}C was added to the medium: aflatoxin B_1 when added was at a final concentration of 0·032 mM. The isolation and determination of radioactivity in the RNA and protein were as previously described[26].

Table 2. Effect of Aflatoxin B_1 on the *in vivo* Incorporation of Orotic Acid-6-^{14}C into the Nuclear RNA of the Liver Cell

	Incorporation into total nucleotides (c.p.m./density unit at 260 mμ)	Incorporation into nuclear RNA (c.p.m./μg RNA.P)	Per cent incorporation into RNA from nucleotide
Control	16,021	1,686	10·5
Control	14,313	2,825	19·7
Aflatoxin B_1	20,180	486	2·4
Aflatoxin B_1	21,477	327	1·5

Rats were poisoned with aflatoxin B_1 and at 3 h after poisoning received a caudal vein injection of ^{14}C-orotic acid in isotonic saline at a dose-level of 12·5 μc./150 g body-weight. They were killed 15 min later and the livers removed. From one portion of the liver nucleotides were extracted[27] and nuclei were isolated from the remainder of the liver from which the RNA was then extracted.

It is known that actinomycin *D* binds to deoxyribonucleic acid (DNA) and thus inhibits the DNA-dependent RNA synthesis[20]. The structure of actinomycin *D* is such that it wedges into a groove of the DNA helix with the quinoidal oxygen—the amino group and the lactone rings undergoing hydrogen bonding. A consideration of the structure of aflatoxin B_1 (refs. 1 and 2), with its three rings and groups capable of hydrogen bonding, suggested that it might bind to DNA in a similar manner. If such a reaction were to occur the DNA would be expected to alter the characteristic absorption spectrum of the aflatoxin B_1. We therefore examined the effects on the absorption spectrum of aflatoxin B_1 of adding varying concentrations of calf thymus DNA and found the difference spectrum showed a similar trace to that given by actinomycin *D* in the presence of calf thymus DNA[20]. The changes in optical density and shift of the absorption peak are given in Table 3.

Table 3. Effect of Calf Thymus DNA on the Spectral Properties of Aflatoxin B_1

Final concentration of DNA (μM DNA.P)	Decrease in *O.D.* at 355 mμ	Increase in *O.D.* at 385 mμ	Molar ratio aflatoxin B_1/DNA.P
397·5	0·085	0·063	0·059
662·5	0·187	0·088	0·035

The final concentration of aflatoxin B_1 was 23·4 μM and this and the DNA were dissolved in 0·01 M *tris*-HCl, *p*H 7·4, containing 0·01 M sodium chloride. Difference spectra were traced using a model 14 serial No. 273, Cary Recording Spectrophotometer[20]. Aflatoxin B_1 has a maximum absorption of 370 mμ in the *tris*-medium; on mixing with the DNA, maximum decrease in absorption is seen at 355 mμ and maximum increase in absorption at 385 mμ. The traces cross the base line from negative difference to positive difference at 377 mμ.

We have further studied the distribution of aflatoxin B_1 in the sub-cellular fractions of the liver cell some 30 min after poisoning and found that, although all fractions show the presence of the toxin, one-third of the total cell content was present in the nucleus.

We therefore propose the following sequence of events following poisoning with aflatoxin B_1: (1) The aflatoxin after entering the liver cell passes into the nucleus. (2) It binds with the DNA and thereby inhibits the RNA polymerase. (3) There is a reduced synthesis of RNA involving an inhibition of messenger RNA as exemplified by the inhibition of the cortisone-induced synthesis of tryptophan pyrrolase. (4) The inhibition of *m*RNA is reflected after some 15 min in a reduced protein synthesis. (5) The continued reduction of *m*RNA production is the cause of the degranulation of the endoplasmic reticulum which has been observed in electron micrographs prepared from the livers of rats poisoned with aflatoxin for 6 h (ref. 21). This would appear to be analogous to the endoplasmic reticulum changes occurring following administration of actinomycin *D* (ref. 22).

In view of the finding that aflatoxin B_1 binds with DNA it may be that the difference in toxicity shown by other varieties of aflatoxin is determined at least in part by the extent to which they are able to bind to DNA.

It is not yet possible to decide to what extent this biochemical lesion is responsible for the development of the periportal necrosis in the livers of poisoned rats. An inhibition of protein synthesis in the liver cell would not *per se* appear to result in hepatic necrosis. This follows from a consideration of the results with rats poisoned with ethionine[23], or *t*-butylmethylnitrosamine[24] or carbon-tetrachloride and treated with promethazine-HCl (ref. 25); in all these cases there is an inhibition of protein synthesis up to 24 h without the development of necrosis. Unlike these agents, however, a single dose of aflatoxin B_1 will depress protein synthesis for at least 48 h, and it may be that in these circumstances the inhibition of protein synthesis could play an important part in the development of the periportal necrosis.

We thank the British Empire Cancer Campaign for Research for a grant which enabled this work to be carried out. We thank Prof. C. Rimington and Dr. M. Tarlow for advice, the Medical Research Council for a gift of the aflatoxin, Dr. W. H. Butler for carrying out parallel histological investigations, and Dr. A. Mathias (Department of Biochemistry, University College, London) for his help in the spectrophotometric determinations.

Influence of Thymic Mass on Murine Viral Leukaemogenesis

THE origin of lymphoma in the thymuses of mice is now well documented[1]. Of interest is the fact that regardless of the means used to induce the lymphoma (virus, chemicals, hormones, X-rays), the pattern of the thymic response is always similar. Recently, in pathogenesis investigations of a virus-induced lymphoma, attention was directed to the thymic anatomy. It was demonstrated that the two 'lobes' of 'the thymus' actually are two separate, paired organs[2–4]. This was of interest because it was noted that the lymphoma change occurred in only one of the two thymuses. Tumour cells frequently disseminated from a tumour-transformed thymus at a time when the opposite thymus was still histologically normal. The process of tumour formation studied histologically in serial sections suggested that the tumour cells evolved throughout a single thymus rather than at a single point[3]. Regarding the thymuses as organs which provide the site for the lymphoma evolution[5], it was of interest to investigate the anatomic unit of thymic tissue necessary for such a change.

To investigate the effect of reduced amounts of thymic tissue in viral leukaemogenesis, new-born random-bred Swiss mice were inoculated with Rich murine leukaemia virus[6], by protocols previously described[3]. At 4–5 days of age mice were either sham-thymectomized, unilaterally thymectomized, bilaterally thymectomized, or left intact. The sexes were equally represented in each group. Uninoculated intact and operated controls were included. The animals were palpated thrice weekly for enlargement of the spleen. When definite splenomegaly was detected, the animal was killed with ether and dissected. The mediastinal contents of mice in which both thymuses had been removed were fixed *en bloc*, and serially sectioned from the level of the thyroid to the bifurcation of the bronchi. In 49 of the 104 bilaterally thymectomized mice, residual microscopic fragments of thymus tissue could be identified histologically by the presence of Hassall's corpuscles, characteristic cortico-medullary differentiation, and the presence of 'PAS' cells. The residual amount of thymus tissue in the serial sections was measured with a calibrated ocular scale. The total volume was estimated by assuming the geometry of a double cone. Assuming a specific gravity of 1·0, the thymus fragments were estimated to weigh between 0·1 and 0·5 mg. By way of comparison, a single thymus of a control animal of comparable age weighed 20–30 mg. The larger fragments were easily visible on the stained slide, but were not discernible in the fresh tissue because they were embedded in mediastinal fatty connective tissue. These 49 animals were designated 'sub-totally' thymectomized. Only animals surviving past the first month were included in the investigation. An additional 51 virus-inoculated and 19 uninoculated, unilaterally thymectomized mice were killed between days 50–75 for pathogenesis examinations.

The results are summarized in Fig. 1. Disseminated thymic lymphoma (lymphoid leukaemia) occurred in

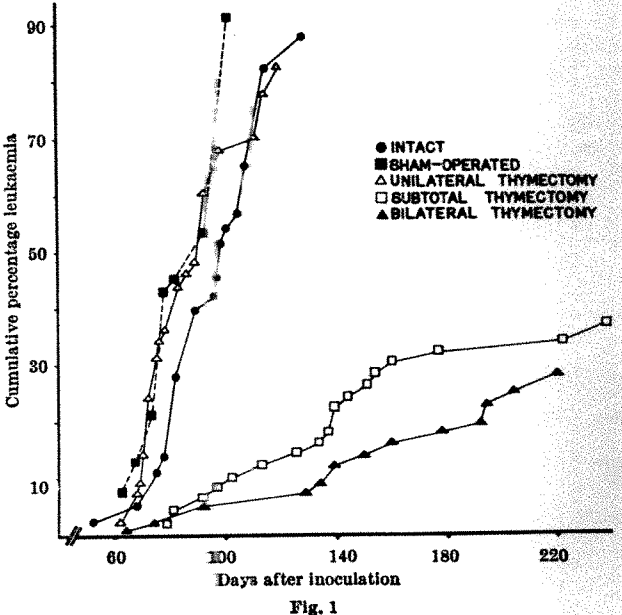

Fig. 1

31 of 35 intact, virus-inoculated mice; 35 of 41 unilaterally thymectomized, inoculated mice; and 14 of 15 sham-operated, inoculated mice. The differences between the mean latent periods in these three groups were not statistically significant. Thus, the incidence and latency of lymphoid leukaemia in mice with one thymus were the same as in mice with two thymuses. Mice possessing less than one complete thymus (sub-totally thymectomized) had a greatly decreased incidence of lymphoid leukaemia (18 of 49) with an increased latent period (137 days versus 91 days in controls).

Although not indicated in Fig. 1, two animals in which definite lymphoma could be seen in residual thymus fragments had concurrent myeloid leukaemia. This finding was also reported by Fiorre-Donati *et al.*[7].

The pathogenesis of the thymic lymphoma in unilaterally thymectomized mice was identical to that in mice with two thymuses, described previously[3]. Briefly, the remaining thymus in unilaterally thymectomized, virus-inoculated mice decreased in size and weight from a control value of 20–30 mg to 10–15 mg between 40 and 50 days. The decrease in weight was reflected histologically by a depletion of thymic lymphocytes and a drawing together of the epithelial reticulum which constitutes the tissue matrix or framework of the organ. Within a few days the contracted primitive cells had begun to proliferate, and formed continuous sheets of large, immature, lymphoblast-like cells. This proliferation was accompanied by a great increase in size and weight of that thymus, often weighing as much as 130 mg. Dissemination of tumour cells to other organs occurred after proliferation had begun. The degree of dissemination and the extent to which the tumour cells proliferated in distant organs was independent of the size of the primary thymic mass. In some instances specimens were obtained with large tumorous supracoecal (mesenteric) lymph nodes, and inconspicuous but completely tumour-replaced thymuses. Because of knowledge of the details of the pathogenesis of this tumour[3], the error of attributing to the largest tumour mass the site of orgin of the tumour was avoided.

No mouse histologically free by serial section of thymus tissue developed lymphoid leukaemia in this investigation during the 240 days of the experiment. Of 55 such mice, however, 16 (28 per cent) developed myeloid leukaemia by day 220 (solid triangles in Fig. 1). The development of myeloid leukaemia in thymectomized, virus-inoculated mice has been previously reported by Gross[8]. In many instances pigment changes in myeloid-infiltrated lymph nodes produced deep shades of green ('chloroleukaemia'). The pathogenesis of the myeloid leukaemia will be presented in a separate publication.

The data indicate that in murine viral leukaemia: (1) thymic tissue is necessary for the evolution of lymphoma, but not for the evolution of myeloid leukaemia; (2) animals with one thymus developed disseminated thymic lymphoma (lymphoid leukaemia) as quickly, as often, and in the same manner, as animals with two thymuses; (3) animals with less than one complete thymus have a markedly decreased incidence of lymphoma, which develops with a longer latency period.

These facts show that while small portions of thymic tissue (0·1–0·5 mg) are capable of evolving the lymphoma, they do so in greatly reduced incidence and after a longer period. While the longer latency may be due merely to the extra time required for a fragment to proliferate enough to make up for its initial small size, the decreased incidence (Fig. 1) suggests that a critical mass of thymic tissue may be a factor in lymphoma change. Study of this factor is now in progress in our laboratory.

We thank Mrs. W. Harrell, Miss J. Geldner and Mrs. S. Siegel for their technical assistance.

BIOLOGY

Inhibition of Fruit Drop and Colour Stimulation with *N*-Dimethylaminosuccinamic Acid

The retardation of vegetative growth of legumes and certain other species by foliar application of substituted maleomic and succinamic acids was reported by Riddell *et al.*[1]. The *N*-dimethylaminosuccinamic acid (designated *B*995) was found to be more stable in aqueous solution than the substituted maleomic[2] and was effective in retarding growth of the same species.

Similar retardation in vegetative growth of apple with foliar sprays of *B*995 has been reported[3]. Another effect of *B*995 application on apple, typical of a growth retardant, is the promotion of flowering of young trees[4]. Brooks[5] has also reported reduction of terminal growth of pear with sprays of *B*995. The spur development correlated with this reduced growth in pear is indicative of increased flowering. In contrast to these effects, tests in 1964 revealed that *B*995 may simulate the action of a growth promoter or auxin in controlling the abscission and pre-harvest drop of mature apple fruits. Auxins such as α-naphthaleneacetic acid (NAA) and 2,4,5-trichlorophenoxy α-propionic acid (2,4,5-TP) have been shown to delay the harvest drop of apples[6] and have been used extensively for this purpose. This report presents the results of several tests which characterize the effects of *B*995 in relation to fruit drop, anthocyanin formation and histological changes in the abscission zone of the fruit pedicel.

Mature apple trees (*Pyrus malus*, Linn. cv. McIntosh) were sprayed at various times and concentrations from full bloom (May 13) to a few days before harvest. From 4 to 8 trees were used per treatment in a randomized block design. Fruit growth measurements were made periodically during the season and fruit firmness, colour and drop data were obtained at the end of the season. Samples were collected from each tree for colour evaluation. Fruit firmness was determined with a Magness–Taylor pressure tester on a sample of 10 fruits from each tree at each harvest date. At normal harvest time for the control trees, fruit drop was occurring and had reached as high as 56 per cent of the total crop in some tests (Table 1).

Table 1. Harvest Drop and Fruit Firmness of McIntosh Apples treated with *B*995

Orchard	Treatment (p.p.m. *B*995)	Date applied (1964)	Fruit drop (%) Sept. 26	Oct. 10	Oct. 26	Fruit firmness (lb.) Sept. 26	Oct. 10	Oct. 26

	Control	—	25·2	—	—	13·7	—	—

* Significantly different from control at 1 per cent probability level.

Trees sprayed with *B*995, even with concentrations as low as 500 p.p.m., had dropped less than 6 per cent of their crop by this date. Drop control was effected with all application dates used in these tests from full bloom until September. However, the late August application, approximately one month before harvest, was the most effective at the lower concentrations of *B*995.

The failure of *B*995 to control drop when applied just prior to harvest as the drop is initiated suggests that the mechanism of control is different from that achieved with auxin sprays such as NAA. With such compounds a delay in abscission and control of drop may occur within a few days after application.

A possible explanation for the control of fruit drop by *B*995 is that softening and maturity of the fruit are delayed and hence the fruits are not so mature as those on untreated trees at the time of conventional harvest. To elucidate this possibility some trees in the various plots were not harvested at the time of picking the control fruits. Pressure data and fruit drop records were obtained on these trees for an additional 3 weeks. The results in Table 1 show that drop was still inhibited on the treated trees even though the fruits had finally softened to the pressure of control fruits when they were picked on September 26 and had experienced heavy fruit drop.

Fruit pedicels and attached cluster bases of the spur were collected from tree units in the various plots on several dates. Freehand longitudinal sections were then prepared through this tissue to show the abscission zone. The distribution of fibres and schlerenchyma cells in the vicinity of the abscission zone was about the same in the pedicels collected from treated trees as from control trees when fruit pressures were comparable (Fig. 1). However, in no case was breakdown apparent in the pith cells of the abscission zone from treated trees. Separation of cells was apparent in the peripheral areas of the abscission zone in pedicels from control trees as well as through the pith in the central portion of this zone (Fig. 1). The absence of this separation and breakdown as the fruits were softening on treated trees would account for the tenacity of the fruit during the harvest period.

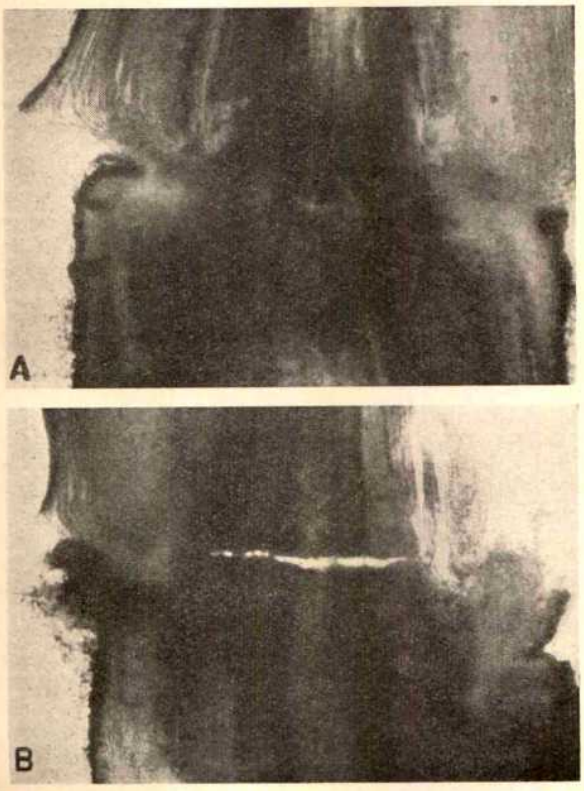

Fig. 1. Photomicrograph of longitudinal section through abscission zone of McIntosh fruit pedicels. (*A*) Treated with *B*995 1,000 p.p.m., August 29. (*B*) Control. Separation of cells and weakening of tissue are visible in control. Specimens collected October 1

It might be expected that anthocyanin formation would be enhanced by application of *B*995 if the fruits remain on the tree longer than the control fruits to reach a given stage of firmness and maturity. The exposure of the fruit to an additional period of light and cool night temperature which promote colour formation would contribute to this phenomenon. Fruits were examined from the replicate trees in the various treatments and the percentage of fruit surface with red colour was determined. The results are shown in Table 2. Intensity of anthocyanin (idaein) in the skin was also determined by optical density measurements according to the method described by Seigelman and Hendricks[7]. A direct colour stimulation by the treatment was indicated in two experiments where comparisons were made on the same harvest date (Table 2).

Table 2. Fruit Firmness and Anthocyanin Formation in McIntosh Apples

Treatment (p.p.m. *B*995)	Date applied	Pressure (lb.)	Surface colour (%)	Anthocyanin ($\mu g/cm^2$)*
		Orchard *Z*, harvested Sept. 14		
500	May 29	16·4†	67	7·9‡
1,000	"	17·1‡	65	7·4‡
5,000	"	19·0‡	74	8·3‡
Control	—	15·9	58	6·9
		Orchard 48, harvested Sept. 26		
500	June 5	16·1‡	80	6·8‡
2,000	"	17·3‡	85	8·0‡
Control	—	14·5	62	6·2

* Expressed as idaein.
† Significantly different from control at 5 per cent probability-level.
‡ Significantly different from control at 1 per cent probability-level.

These results thus show that delay in fruit abscission, an unexpected response of the application of a growth retardant, is not dependent solely on the delayed maturation of the fruit. Changes in the abscission zone occur which may inhibit separation of fruit pedicel from spur beyond the stage of maturity characteristic of control fruits at abscission. Firmer fruit at a given calendar date and enhanced formation of anthocyanin are likewise associated with this treatment.

We thank Mr. Paul Bohne, Naugatuck Chemical Division, for supplying the *B*995 used in these tests. The work was supported in part by a grant from Naugatuck Chemical Division, Bethany, Connecticut.

Germ Cell Migrations in a Cestode

Usually in cestodes the potential oocytes and associated cells of the female system leave the germinal primordium in the median line of the proglottid while the cells are still either undifferentiated or not easily distinguishable. In a member of the problematical order Tetrabothridea, oogonia, true vitelline cells, and what are considered to be shell-producing cells of two kinds, differentiate within the female primordium, although the whole process is delayed in this worm because of marked protandry. This delay causes the process of germ cell differentiation to coincide in time with the differentiation of the uterus, and the latter can thus be identified, for the first time, as the outer layer of the primordium enclosing the germ cells

except for a posterior aperture (Fig. 1). The shell-producing cells and oogonia migrate through this aperture in an organized sequence: first the compact gland cells, usually called 'vitelline', then the cells of a diffuse gland similar to those of the follicular glands of Pseudophyllidea, also usually called 'vitelline', and finally the oogonia. The true vitelline cells, arranged in the primordium in rosettes around the oogonia, degenerate within the primordium. The three sets of migrating cells, some of which were seen to be amoeboid, travel progressively less far into the medulla, which is itself differentiating at the same time (Fig. 1). The distance covered by the migrating cells would appear to be related to this medullary differentiation and thus indirectly to the degree of protandry. The migrating cells form two organs and not three as the diffuse gland contains both shell-producing cells and oogonia (Fig. 1).

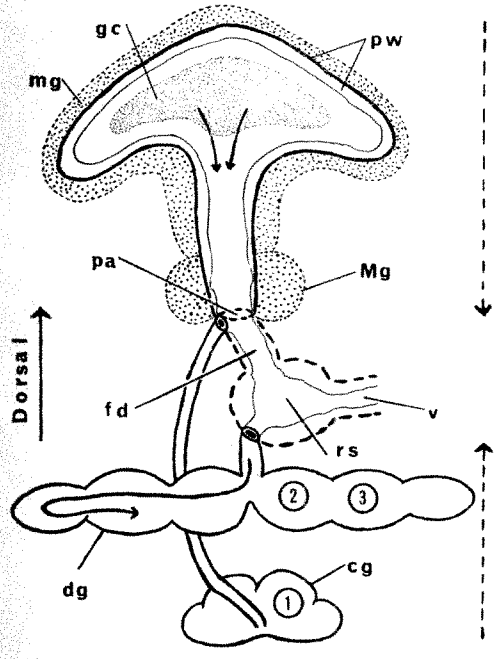

Fig. 1. Diagrammatic representation (not to scale) of morphogenesis of female primordium of *Tetrabothrius erostris* (Lönneberg). *c g*, Compact gland; *d g*, diffuse gland; *f d*, fertilization duct; *g c*, germ cells; *m g*, medullary gland cells; *M g*, Mehlis's gland; *p a*, posterior aperture; *p w*, fibroblast wall of ♀ primordium = wall of germarium = wall of uterus; *r s*, receptaculum seminis; *v*, vagina. Continuous arrows indicate movements of germ cells: (1) compact gland cells; (2) shell-precursor cells; (3) oocytes. (2) and (3) occur in both lobes of the diffuse gland. Dotted lines represent the latest proliferation of wall cells of primordium. Dotted arrows indicate direction of differentiation of medulla

During the development of the primordium into such a temporary germarium the whole is surrounded except for the posterior aperture by medullary gland cells secreting into it. When the germ cells are all expelled these gland cells cease to function except for a group, which becomes Mehlis's gland, around the posterior aperture. During the process the posterior aperture moves backwards so that the primordium becomes T-shaped (Fig. 1). The wall cells around the aperture proliferate to form the duct system along the route of the migrations and in addition forms a duct which has no precursors, the vagina. At this stage the posterior aperture of the primordium is recognizable as the so-called ootype which thus represents the posterior extremity of the uterus. The reproductive pattern is therefore determined by the timing of germ cell migrations, representing an epigenetic pathway of considerable biological significance.

All the medullary gland cells are periodic acid–Schiff-positive (with glycogen excluded) while they are functional and thus quite distinct from the rest of the medulla. Mehlis's gland is therefore thought to function in two phases in this worm; first, around the primordium while proliferation, differentiation and movement of germ cells occur; secondly, around the posterior aperture while this proliferates to form the duct system, persisting until embryonation occurs in the uterus. It is interesting that Rao[1,2], working on the chemistry of Mehlis's gland in *Fasciola hepatica* and in a pseudophyllidean cestode, considers the secretion to be a lecithin-like phospholipid involved in yolk formation in the uterus while embryos are being formed. This is the only place where the Mehlis secretion would have been expected to be found, as it is generally assumed that the germ cells pass through the region of Mehlis's gland only in one direction. I make the suggestion, based not on chemical evidence but on an embryological interpretation, that the secretion from the gland cells around the entire primordia, including the later restricted Mehlis's gland, may be the ultimate source of vitelline material for the proliferation and maintenance of the whole female reproductive complex. Such information about morphogenesis would be unavailable in forms where differentiation of the female system is extended in time by early germ-cell migration made possible by the evolution of a strongly polarized strobila of considerable length and the overlapping, in time, of the differentiation of male and female sex cells.

Early migration of germ cells, characteristic of most modern cestodes, would thus seem to be correlated with the more effective production of shell materials used as individual egg coverings and inversely related to egg protection by an elaborated uterus wall which, by definition, must have been primitively a closed structure with correlated apolysis. The Tetrabothridea, though considerably specialized in their modern form, combine significant characters of Cyclophyllidea, Pseudophyllidea and Tetraphyllidea, and these same characters are linked through *Tetrabothrius erostris* with many aberrant forms which collectively possess the following inter-related features which I believe to be basic to cestodes, namely: (1) no migration of female germ cells; (2) a closed uterus and permanent germarium; (3) apolysis and fragmentation associated with limited polarity; (4) marked protandry or the dioecious condition. On a basis of these characters, and on evidence leading to the conclusion that the primary organizer defines not three layers but two, namely, germinal and somatic, it is possible to construct a hypothesis for strobila organization which does not conflict with the reproductive metamerism theory of Hyman[3] and takes account of the elements of the zooid theory of earlier workers, while at the same time it supports the views expressed by Stunkard[4]. This hypothesis and the evidence supporting it will be presented in detail in a later publication.

Proteolytic Enzymes of *Citellus citellus* and *Spalax leucodon*

With present knowledge and techniques, a more meaningful application of biochemical data towards classification schemes may be made at the family level and lower[1].

We have found it interesting to compare, from the biochemical aspect, two species of the order Rodentia which belong to different sub-orders[2], namely, families sub-order Sciuromorpha—fam. Sciuridae (*Citellus citellus*), and sub-order Myomorpha—fam. Spalacidae (*Spalax leucodon*).

According to recent taxonomy, these two families are phylogenetically very distant. *Spalax leucodon* is especially interesting, because of its origin (a very old species in this order—first data are from Oligocene) and specialized way of life.

All animals killed before investigation spent about one month under laboratory conditions. Food of *Spalax leucodon* was similar to that found in its natural environment (potato, onion, carrot); food of *Citellus citellus* consisted of grains of wheat, carrot and cabbage.

The tissue homogenate of the duodenum with a part of pancreas of both animals examined contained 8 mg duodenum and 1·87 mg of pancreas per 1 ml. of distilled water.

Proteolytic activity was determined by the casein digestion method[3]. The reaction was initiated after 5 min of equilibration at 37° C by addition of soluble casein to a concentration of 0·5 per cent in the following buffers: 0·075 M phosphate *p*H 6·0, 6·5, 7·0, 7·5 and 8·0. Enzymatic activity was terminated after 20 min incubation at 37° C by addition of 5 per cent trichloroacetic acid. Optical density was determined in filtered solutions at 280 mμ.

The relative protein content in each case was determined with the phenol reagent described by Lowry *et al.*[4]. All results were calculated on the same protein basis.

Results are shown in Fig. 1. From the graph, it is evident that protease activity of the duodenum with a part of pancreas differs in *Citellus citellus* from that in *Spalax leucodon* in relation to changes in *p*H. Protease activity of *Citellus citellus* at all points is much higher than that of *Spalax leucodon*: for example, maximal protease activity is about 3 times higher in *Citellus citellus* than in *Spalax leucodon*.

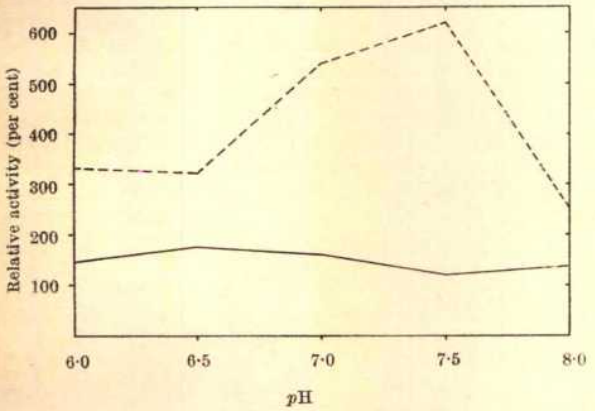

Fig. 1. Protease activity of the duodenum and part of pancreas of *Citellus citellus* and *Spalax leucodon* in relation to *p*H of the reaction mixture. - - -, *Citellus citellus*; —, *Spalax leucodon*

It is well known that the effect of *p*H on enzyme activity is highly important in studying enzymes, even though a satisfactory explanation of the effect is not available[5].

Protease activity of *Citellus citellus* under the conditions described is dependent on the *p*H of reaction mixture (optimum *p*H 7·0–7·5). On the contrary, protease activity of *Spalax leucodon* is not, in general, dependent on the *p*H of reaction mixture; under the same conditions it is more or less on the same level.

This fact may suggest differences between the nature of protease of these two species of Rodentia.

The cause of the aforementioned differences in protease activity between these two species must still be considered as unexplained. We have tried to consider it from two aspects.

It is known that high protein diet results in pancreatic juice, high in trypsin and chymotrypsin[6–8]. Maybe the difference in protease activity could be partially explained by differences in their food (*Citellus citellus* takes food which is richer in proteins than *Spalax leucodon*).

On the other hand, the very unusual form of curve of protease activity of *Spalax leucodon* suggests a connexion with the specialized way of life of this animal, which belongs to the family Spalacidae. In the evolution of order Rodentia this family appeared very early in the Oligocene, which is undoubtedly also reflected in its biochemical system.

Our unpublished results on alkaline phosphatases of the species examined also prove the same.

Membrane in the Human Tooth

The inner structure of human teeth, the dentine, is occupied by the dental pulp. This is generally described as a syncytium, cell tissue in which the cell walls are not clear, though the outermost layer of the pulp consists of a well-defined layer of cells, the odontoblasts, firmly attached to the dentine.

An early investigation of cells and membranes in teeth[1] was followed by similar studies[2], almost all being of histological nature; interest in biological activity of membranes in general has increased. It was noted[3] that "the pulp tissue appears to be bounded by a membrane"; demonstration was incomplete. Further evidence has now been obtained from freshly opened human teeth, when the pulps were removed and examined by electron micrography.

A membrane composed of two layers about 100 Å apart is seen to surround the pulp (Figs. 1 and 2), lying between the body of the pulp and the layer of odontoblasts. When a pulp is removed from a tooth, the neighbouring cells —the odontoblasts—remain *in situ*[4]; this is not shown in the specimens illustrated.

Labelled ions (^{32}P as PO_4) pass through human teeth[5]. passage now being found to be part active, part passive, Ion transfer and the membrane are subjects of further inquiry; a fuller account is in preparation.

Fig. 1. ×, 6,000

Fig. 2. × 18,000

The E.M.F. of the membrane surrounding the human dental pulp was determined by the use of micropipettes; it has a value of about 45 mV.

Selective Inhibition of Cation Absorption by Uranyl

Investigations into the interactions between cations in the ion absorption process of plant roots resulted in the observation that uranyl (UO_2^{++}) appeared to produce a differential inhibition of the uptake of certain cations. The only information found in the literature concerning such a differential effect by uranium was that reported by Rothstein[1]. He showed that uranium, in the form of uranyl chloride, inhibited the uptake of hexoses by yeast cells while having essentially no effect on the uptake and metabolism of other substrates such as alcohol and pyruvate. In the light of these observations detailed experiments were conducted to evaluate the effect of UO_2^{++} on the metabolic absorption of Li^+, Na^+, K^+, Mg^{++} and Mn^{++} by excised barley roots.

Barley seedlings (*Hordeum vulgare*) were grown and the experiments were conducted according to the methods outlined by Jacobson *et al.*[2]. The roots were placed into continuously aerated test solutions maintained at *p*H 5·0 and at a temperature of 25° C. At the end of the absorption period the roots were removed from the solution, washed with distilled water, dried overnight, and digested in nitric and perchloric acids. Li^+, Na^+ and K^+ were determined by flame photometry and Mg^{++} and Mn^{++} by atomic absorption spectrophotometry. (Due to the toxicity of uranium these instruments should be placed in a well-ventilated fume hood.) Standard solutions with and without UO_2^{++} were compared and interferences in the analyses were found to be negligible.

Previous work has shown that ion uptake by excised barley roots occurs in two phases. The first phase is a non-metabolic uptake into the apparent free space, whereas the second phase is associated with steady-state metabolic uptake. Only the metabolic uptake was evaluated in this study. Metabolic uptake of ions by barley roots reaches a steady state prior to 1 h and maintains this rate for periods in excess of 6 h. The rate of uptake was measured as the difference in uptake between a 1-h and a 6-h absorption period. All results are expressed in milli-equivalents uptake per kilogram of fresh root tissue per 5 h (m.equiv./kg/5 h). Differences between treatments of ± 1 m.equiv./kg/5 h are significant.

Table 1 presents the results of these experiments. The effects of adding 1·0 m.equiv. UO_2^{++}/l. to the test solution can be seen by comparing the first two columns in Table 1. From these results it is apparent that UO_2^{++} had considerably different effects on the various cations. Uranyl had essentially no effect on the uptake of Li^+, reduced Na^+ by 36 per cent, K^+ by 74 per cent, Mg^{++} by 83 per cent and Mn^{++} by 69 per cent.

The effect of pretreating the roots with UO_2^{++} prior to the absorption period was also evaluated. Roots were pre-treated by placing them into a solution of 1·0 m.equiv. UO_2^{++}/l. for 30 min. After the pre-treatment the roots were thoroughly washed in distilled water and then placed into the test solution. Except for the pre-treatment, these roots were handled in an identical fashion to the control roots. During the pre-treatment, approximately 5 m.equiv. UO_2^{++}/kg roots was bound by the tissue and was not removed by the distilled water wash. This UO_2^{++} was apparently bound very tightly since the bulk of it was still associated with the tissue at the end of the subsequent absorption periods. The data showing the effect of UO_2^{++} pre-treatment are given in the last column of Table 1.

Although the inhibitory effect of the UO_2^{++} pre-treatment was not as pronounced as the effect of including the UO_2^{++} in the bottle with the test solution, there was still considerable difference between the reaction of the various cations. Mn^{++} was unaffected by the pre-treatment; Li^+ and Na^+ were either unaffected or slightly stimulated; whereas K^+ and Mg^{++} still showed the inhibitory effects of UO_2^{++}.

Table 1. The Effect of Uranyl (UO_2^{++}) on the Uptake of Cations by Excised Barley Roots. (All Ions were present at 5 m.equiv./l. except for UO_2^{++} which was present at 1 m.equiv./l.; Pre-treatment was for 30 min in a 1 m.equiv./l. UO_2^{++} Solution; all Ions were provided as Chloride Salts)

Ion	Net uptake (m.equiv./kg/5 h) Control	+ UO_2^{++}	Pre-treatment
Li	9·0	8·1	11·7
Na	24·4	15·7	26·6
K	27·8	7·3	18·5
Mg	12·6	2·2	6·0
Mn	7·4	2·3	7·2

Dinitrophenol (DNP) and low temperature were used to determine if the portion of the ion uptake which was resistant to UO_2^{++} was metabolically mediated. 5×10^{-5} M DNP was found to completely inhibit the absorption of Li^+, Na^+ and K^+ in the UO_2^{++} treatments as well as in the control. Low temperature (0·5° C) was used in an independent verification of the metabolic nature of K^+ and Na^+ uptake. In this experiment low temperature almost completely inhibited the uptake of these two ions by both pre-treated and control tissues.

From the results obtained in the work recorded here, UO_2^{++} appears to hold promise as a means of separating and characterizing various cation transport sites. Unlike the common inhibitors of ion absorption (metabolic poisons, low temperature and anaerobiosis), UO_2^{++} shows a considerable degree of selectivity. This selectivity strongly suggests that UO_2^{++} reacted with specific sites intimately involved in ion absorption rather than interrupting some basic aspects of respiration which supplies energy for the general ion transport mechanism. This hypothesis is supported by the observation that the UO_2^{++}-resistant

absorption was inhibited by dinitrophenol and low temperature. Furthermore, the strong retention of UO_2^{++} by the tissue and the persistence of the effect of UO_2^{++} on certain ions following pre-treatment indicates that UO_2^{++} was probably bound tightly to some of these active sites.

Of particular interest is the differential effect that UO_2^{++} had on Na^+ and K^+ absorption, especially the effect of pre-treatment. Na^+ and K^+ are chemically similar and exhibit similar absorption characteristics in barley roots[3]. In contrast to animal systems, both cations may be accumulated inside plant cells, and are known to compete readily during absorption by this kind of root tissue[4]. In this work, K^+ was inhibited to a much greater extent than was Na^+; therefore, it seems reasonable to conclude that at least a portion of the Na^+ transport was handled differently than K^+ transport by this tissue. Although these roots initially contained more K^+ than Na^+ the loss of K^+ due to UO_2^{++} treatment was slight and cannot account for the observed differences.

The results with cation absorption are similar in many respects to the UO_2^{++} induced differential inhibition of the uptake of organic substrates by yeast cells as reported by Rothstein[1]. He concluded that the UO_2^{++} was bound tightly at the yeast cell surface and did not penetrate into the interior of the cell. Numerous substances in the cell are capable of binding UO_2^{++} (ref. 5). Phosphate, a constituent of many compounds present in the cell membrane, has a high affinity for uranyl. This high affinity of phosphate for uranyl may be significant in the light of recent speculation concerning the role of phosphorus compounds in the ion absorption process[6].

Depressant Effect of Moonlight on Activity of Aquatic Insects

Investigations by Waters[1], Müller[2-5], and Wickett[6] have conclusively demonstrated the diurnal periodicity of downstream drift of aquatic insects and other invertebrates. Prior to these investigations, Moon[7] had shown that the nocturnal activity of aquatic insects is much greater than that observed during the day. Very little data are available to demonstrate whether these activity-levels are circadian rhythms or whether they are a direct response to the level of light intensity. Beeton[8] observed a depression of the vertical migration of the freshwater shrimp, *Mysis relicta*, due to increased moonlight. Waters[1] suggested that the magnitude of the nocturnal drift rate may be, in part, a function of moonlight. The following data appear to support Waters's contention.

Collections of aquatic insects drifting downstream were taken at intervals of 3 weeks during 1963 and 1964 in Berry Creek, near Corvallis, Oregon (lat. N. 44° 43′, long. W. 123° 16′). These collections were made as part of a project concerned with measuring the production rate and energy exchange in a woodland stream community.

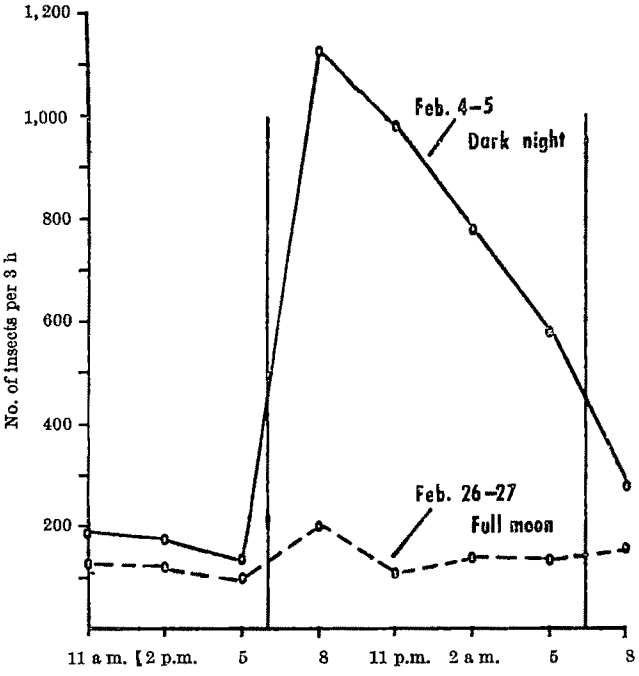

Fig. 1. Number of insects (Ephemeroptera, Plecoptera, and Simuliidae) collected per 3-h sampling interval on a dark night and a moonlit night. The vertical lines indicate approximate times of sunset and sunrise

The data reported here compare results from two consecutive collecting dates, February 4–5 and February 26–27, 1964. It is felt that differences in drift rate can be attributed to differences in intensity of moonlight on the two nights. The night of February 4–5 was clear, but dark, with the Moon in the last quarter, rising at 0012 Pacific Standard Time, and setting at 1118; on February 26–27, the night was again clear, but bright, as the full moon rose at 1659 and set at 0728. Weather and stream conditions for the two days were similar. Mean water temperature for the former was 8·3° C, and for the latter, 6·7° C.

The total numbers of insects in the three dominant taxa, Ephemeroptera, Plecoptera, and Simuliidae, collected during each 3-h sampling interval on the two dates are compared in Fig. 1. Chironomidae are abundant in Berry Creek and are an important component of the drift, but are not included because there was no evident increase in their drift rate at night. The drift rate of the dominant taxa for February 4–5 exhibited the typical pattern (compare Waters[1]), with a sharp increase occurring shortly after sunset, followed by a gradual decrease during the night. The drift rate during both day and night was nearly constant on February 26–27, with little or no evidence of the expected sharp post-sunset increase.

Table 1. Percentage of Larvae (Ephemeroptera, Plecoptera, and Simuliidae) 3 mm or Larger in Drift-trap Collections

	February 4–5 (dark night)	February 26–27 (moonlit night)
8–11 a.m.	17·9	18 6
11–2 p.m.	12·4	17·4
2–5 p m.	16 2	11·5
5–8 p m.	42 3	18 3
8–11 p.m.	41·5	28 1
11–2 a.m.	30 3	15 7
2–5 a m.	23 0	19 3
5–8 a.m.	11·5	12·4

The range of size of organisms collected was from 0·5 to 7·0 mm in length. Table 1 gives the percentage of insects over 3 mm in length collected during each sampling interval; these are arbitrarily considered 'large' insects. There is a high correlation between the increase in the percentage of these large insects and the post-sunset increase in drift rate on February 4, whereas on the moonlit night a much lower percentage of larger forms occurred

in the drift. Comparing the total night period (5 p.m. to 5 a.m.) with the daylight period (5 a.m. to 5 p.m.), the percentage of large insects in the drift was: February 4–5, day—14·1, night—36·1; February 26–27, day—16·0, night—19·0. There was no major emergence of adult insects between the two sampling dates that could have accounted for a decrease in mature insects; it is expected that there should be some slight increase in mean size due to growth at that time of year.

On the basis of the present set of observations, the diel periodicity of drift rate appears to be a direct response to lowered light intensity at sunset. The depressant effect of moonlight on drift rate results from the suppression of activity of the larger size classes of larval insects. Feeding behaviour and other activity patterns associated with periods of low light intensity may have evolved as a protective or avoidance mechanism to escape attack by predators that seek their prey visually.

Differentiation of Nucleated Red Blood Cells during *in vivo* Culture of Mouse Spleen and Thymus Cell Suspensions

Differentiation of nucleated red blood cells has been observed when mouse bone marrow was cultivated *in vivo* in diffusion chambers[1]. Recently, during investigations of the survival of thymus and spleen cells similarly cultured, we found that differentiation of nucleated red blood cells also occurred. This was indicated by an increase in the number of erythrocytes after cultivation. The present report describes these findings.

Healthy male mice of the *BALB/cfSp* strains, 7–9 weeks of age, were used throughout. In experiment 1, six donor mice were used for each time period; in experiment 2, five donor mice were used. One chamber was inserted into each age-matched recipient mouse. All mice were killed by cervical dislocation.

The diffusion chambers were modified from those used by other workers[2,3]. They were constructed of 'Plexiglas' rings (16 mm outside diam., 9·5 mm inside diam., 2 mm thick, access hole 1 mm diam.) sandwiched between two filters. Filters were Schleicher and Schuell *B*-14 'BAC-T-Flex', having an average pore diameter of 0·1μ. The membranes were sealed to the rings with Rohm and Haas 'Acryloid *B*-7' cement. Chambers were allowed to dry for at least 18 h and then sterilized for 72 h at 78°–80° C dry heat. Each chamber, when completed, had an average volume of 0·14 ml. Empty chambers prepared in this manner and with the access hole sealed with a chip of heat-softened 'Plexiglas' were found to be completely unpenetrated by cells 5 days after they were inserted into the peritoneal cavity of recipient mice.

Donor mice were killed, washed in a 0·94 per cent Wescodyne solution and the thymus and spleen (experiment 1), or only the thymus (experiment 2), were removed. Cells from each organ were obtained by gentle dispersion in 0·4 ml. of Krebs–Ringer phosphate buffer solution fortified with Eagle's nutrients and adjusted to *p*H 7·3–7·4 (KRP) in a 1-ml. centrifuge tube by means of a 5-mm glass rod, tapered to fit snugly in the tube. The KRP had been sterilized by passage through a Millipore *HA* filter. The resulting suspensions were transferred aseptically to 12-ml. centrifuge tubes and diluted to 1 ml. Following thorough dispersion, a portion was removed and the cellular content of each suspension was determined. KRP was then added to adjust the cell density to 50–100 million cells per ml. Few broken or clumped cells were found on microscopic examination of suspensions prepared in this manner.

Recipient mice were anaesthetized with ether and the peritoneal cavity opened with a small incision of the midventral surface of the animal. The chambers were filled with 0·1 ml. of the organ suspensions, the access hole was sealed with a chip of softened 'Plexiglas' and the chamber was inserted into the abdominal cavity of the recipient. At the same time an aliquot of each suspension was taken for a repeat count and another portion was used for making a smear for the differential count. The recount was made to correct for possible changes in the cell content of the suspensions during the interval between the first count and the time the cells were inserted into the chambers.

The recipient mice were killed at various times after chamber insertion. The chambers were removed, their outer surfaces cleared of adherent host cells, then washey in KRP and wiped dry. One of the filters was carefulld removed and the entire content was transferred to a 5-ml. centrifuge tube and dispersed gently with a glass rod. A portion of the fluid removed was thoroughly mixed with an equal amount of KRP and a total cell count was made. The remaining portion was used for a differential count.

All smears made for differential counts before and after culture were air dried. In experiment 1, they were stained with haematoxylin and eosin; in experiment 2, they were stained with freshly prepared buffered Leishman's stain. A minimum of 100 consecutive cells were examined and the proportion of erythrocytes was determined. The total number of erythrocytes in the chambers before and after culture was then calculated from the total cell counts.

Marked variation was found in the number of erythrocytes in the donor organs and in the number of cells converted to erythrocytes (Tables 1 and 2). At all the times studied, the average number of erythrocytes in cultured spleen (Table 1) and thymus cell (Table 2) suspensions was increased. Such an increase was found in 18 of 24 (75 per cent) spleen and 23 of 29 (79 per cent) thymus cultures. Considerably more spleen than thymus cells

Table 1. Differentiation of Red Blood Cells during *in vivo* Culture of Spleens in Diffusion Chambers

Days after insertion	Total No. of cells inserted into chambers	No. of erythrocytes when implanted	No. of erythrocytes when removed	Cells converted to erythrocytes (per cent)
		Experiment 1

were converted to erythrocytes (Tables 1 and 2). Of the former, the number of cells converted was greatest after one day of cultivation; of the latter, the greatest number of cells converted occurred after 3 and 5 days of culture. These findings indicate that the process of erythroid maturation was longer in the thymus than in the spleen.

The reasons for the marked variations are not apparent at the present time. They may merely indicate that, although the mice belonged to a highly inbred strain, environmental conditions resulted in a different requirement for erythropoiesis in each mouse in reticuloendothelial sites other than the bone marrow. Alternatively, red blood cell formation may be a rhythmic process and the variations may result from the fact that erythropoiesis in the spleen and thymus of each mouse was at different stages of such a cycle at the time they were killed. These possibilities are at present under investigation.

The data suggest several conclusions. First, it is apparent that differentiation of nucleated red blood cells from spleen and thymus can occur during *in vivo* culture in diffusion chambers. Secondly, erythropoiesis in reticuloendothelial sites other than bone marrow normally is a common occurrence in healthy young adult male mice and may be quite extensive since as many as 62 per cent of the spleen cells were found to have an erythropoietic function. Inasmuch as bone marrows from comparable mice were normal, the possibility that the presence of nucleated red blood cells in the spleen and thymus is due to extramedullary hematopoiesis can be excluded. Thirdly, the thymus is an important site of erythropoiesis since as many as 18 per cent of its cells may have this function. This finding is in agreement with previous observations[4]. Fourthly, maturation of erythrocytes appears to differ in the thymus and the spleen. Fifthly, many of the cells in these organs, especially in the thymus, have been erroneously identified, in the past, as lymphocytes.

ENTOMOLOGY

Intersterility as a Consequence of Insecticide Selections in *Tetranychus urticae* Koch (Acari : Tetranychidae)

In July 1961 specimens from a wild colony of *Tetranychus urticae* were gathered from *Sambucus nigra* L. in dunes in the Netherlands and cultivated on beans (*Phaseolus vulgaris* L.) in the laboratory. This colony (*S*) proved to be very susceptible to the ovo-larvicide 'Tedion' (2,4,5,4′-tetrachloro-diphenylsulphone—LD_{50}, 1·410 p.p.m.).

In 1961, a series of selections on a representative sample of this colony with the compound 'Tedion' resulted in a strain R_1, highly resistant to 'Tedion'. Three years later a second series of selections was performed, also obtained from the original colony, and a resistant strain R_2 was acquired.

A genetic analysis of resistance to 'Tedion' could not be executed, since an unexpected intersterility existed between the *S*- and *R*-strains[1]. In Table 1 the percentages of sterile eggs in the F_1 and F_2 progeny are given for all combinations of crosses.

As *T. urticae* has a generative parthenogenesis[2], I was able to establish the sterility of the haploid eggs in the F_2 separately by starting from unmated F_1-females. The opposite, a purely diploid progeny, cannot be obtained, as the mated females always gave a mixture of diploid and haploid eggs.

Table 1. Percentage of Sterile Eggs of Several Combinations of Crosses between Resistant Strains (R_1 and R_2) and the Wild Colony (*S*)

Mass crossing ♀×♂	F_1 diploid and haploid		F_2 diploid and haploid		F_2 haploid	
	Eggs	Sterility (%)	Eggs	Sterility (%)	Eggs	Sterility (%)
$S \times S$	559	6	453	7	311	6
$R_1 \times S$	390	7	566	26	516	31
$S \times R_1$	772	12	309	40	559	61
$R_1 \times R_1$	493	2	412	8	547	8
$R_2 \times S$	716	2	431	19	657	33
$S \times R_2$	685	3	324	28	648	62
$R_2 \times R_2$	282	3	706	4	656	5
$R_1 \times R_2$	267	3	—	—	162	6
$R_2 \times R_1$	282	3	—	—	187	1

The outstanding fact that arises from these observations is that selection with an insecticide has resulted in an appreciable genetic blockade. The intersterility factors accompany on both occasions the build-up of resistance in strains R_1 and R_2. The specificity of the intersterility is underlined by the lack of sterile eggs in the mutual crosses of R_1 with R_2.

The phenomenon of a decreased genetic affinity following the application of an insecticide has not, so far as I know, been reported before. It is interesting from the point of view of theories of evolution and also because it has consequences in the practical control of spider-mites.

A further analysis of 'Tedion' resistance and intersterility is being undertaken.

MICROBIOLOGY

Stabilization of Autolysis in *Bacillus cereus* T

During investigations of the tricarboxylic acid cycle in intact, resting vegetative cells of *Bacillus cereus* T suspended in phosphate buffer, spontaneous autolysis was observed similar to that reported by Kronish *et al.*[1] in 0·05 M *tris* (hydroxymethyl)-aminomethane (*tris*) buffer, *p*H 7·5. Further examination of intact, resting cells was precluded unless the cells could be stabilized, remaining metabolically active for the required duration, usually 2–4 h, and preferably in the absence of agents such as sucrose or polyethylene glycol 4000 (ref. 1).

Since analysis in a marine pseudomonad can be prevented or reduced by several cations, principally Mg^{++} (refs. 2 and 3), a similar situation might prevail in *B. cereus* T, and consequently the effect of Mg^{++} on autolysis in this organism was investigated.

B. cereus T was grown in 'Trypticase Soy Broth' (Baltimore Biological Laboratory) from a suspension of germinated spores[4] for 4 h at 30° C. Cells at the filamentous stage of development[5] were collected by centri-

fugation, then washed twice with and suspended in 0·05 M *tris* buffer, *p*H 7·5, containing the appropriate concentration of $MgSO_4$, and shaken at 30° C. The cell suspensions were examined turbidimetrically at 600 mμ in a Bausch and Lomb Spectronic 20 colorimeter and by phase-contrast microscopy. Viability determinations were made on 'Trypticase Soy Agar' with the same concentrations of $MgSO_4$ in the dilution tubes as in the test suspending medium.

Above 0·05 M $MgSO_4$ the absorbency of the cell suspension increased over a 4-h period as compared to the initial reading (Fig. 1), suggesting a possible increase in the number or size of the cells or a change in the optical properties of the cells with increasing osmolarity[6,7]. Phase-contrast microscopy of the suspensions after 4 h indicated a large but variable number of spheroplasts at 0·05 M and 0·1 M. At higher concentrations there was an increasing proportion of shortened, partially refractile cells, relatively few spheroplasts identifiable as such, and numerous bright, round bodies that may have been spheroplasts modified optically by the relatively high solute concentration[6,7].

Relatively high degrees of viability were maintained for 2 h at all concentrations, 0·05 M and 0·1 M being the best in this regard (Fig. 2). After 4 h, however, the reduced viability at these concentrations may have resulted from spheroplast sensitivity to plating since respiratory activity at these lower concentrations decreased only moderately during the latter hours of the experiment, when most of the cells were spheroplasts.

Q_{O_2}, highest at 0·05 M and 0·1 M, decreased with increasing hypertonicity (Table 1), which is consistent with the decreased viability at these concentrations.

The increase in absorbency of the resting-cell suspensions at higher $MgSO_4$ concentrations would seem to be related to a combination of spheroplast formation[8] and a change in the optical properties of the cells in hypertonic solutions rather than to any substantial increase in cell numbers. The lower concentrations of $MgSO_4$, 0·05 M and 0·1 M, can then be used to maintain resting vegetative cells of *B. cereus* T in a sufficiently active metabolic state for several hours. Whereas Mg^{++} apparently is involved in maintaining the integrity of the spheroplast, it does not prevent enzymatic autolysis[9] from occurring. But it may be involved in delaying autolysis since the rate of spheroplast formation appeared to be lower than the corresponding decrease in turbidity in the *tris* control. The system described could be quite useful for studying cell-wall degradation at a depressed rate as well as for gaining insight to the problem of spheroplast integrity.

Stabilization is not necessarily restricted to hypertonicity alone; other factors are being examined and will be reported on later.

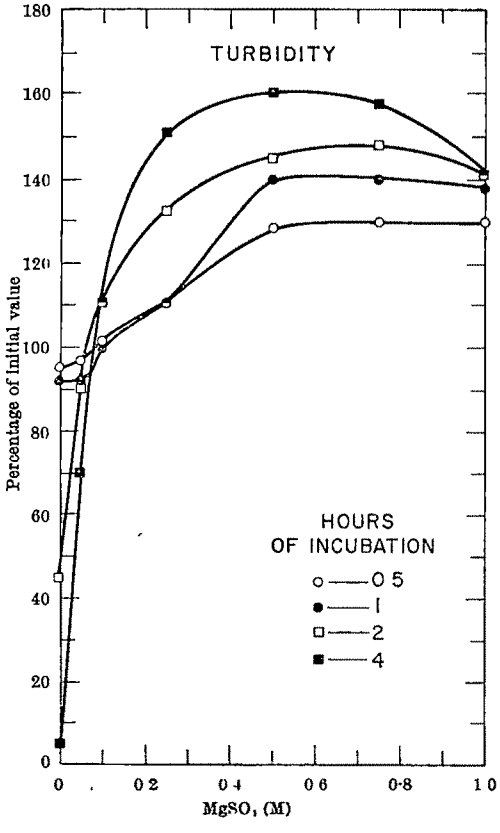

Fig. 1 Effect of $MgSO_4$ molarity on turbidity of resting-cell suspensions of filamentous stage *Bacillus cereus* T. Suspending medium consists of 0 05 M *tris* buffer, *p*H 7·5, and the appropriate concentration of $MgSO_4$

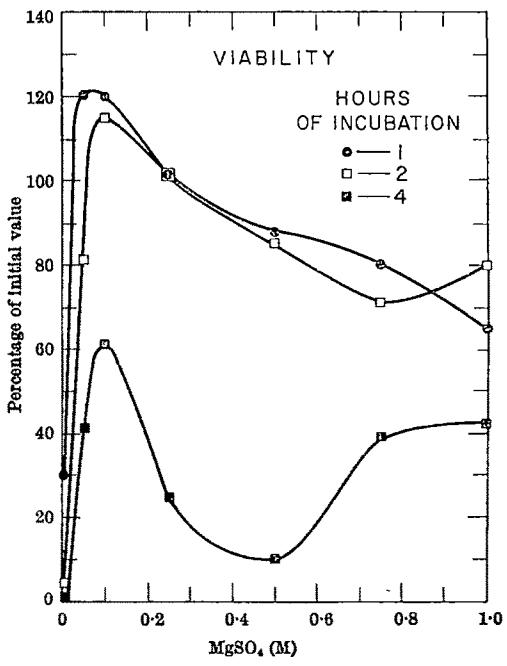

Fig. 2. Effect of $MgSO_4$ molarity on viability of resting-cell suspensions of filamentous stage *Bacillus cereus* T. Suspending medium consists of 0 05 M *tris* buffer, *p*H 7·5, and the appropriate concentration of $MgSO_4$

Table 1. Effect of Magnesium Sulphate Molarity on Q_{O_2} of Resting-cell Suspensions of Filamentous Stage *Bacillus cereus* T

$MgSO_4$ (M)	Q_{O_2} (μl./O_2/h/mg dry wt.)
0·05	108·2
0·1	97·2
0·25	81·7
0·5	48·5
0·75	25·1
1 0	8·3

Tris control omitted because of rapid lysis and concomitantly low respiration.

VIROLOGY

Inhibition of Haemagglutinating Particles of Coxsackie *B5* Virus by HeLa Cell Cultures

It has been observed in recent years that many enterovirus strains (belonging to 18 types[1,2]) have the ability to agglutinate human red cells.

The receptor of human erythrocytes for some ECHO viruses is destroyed by chymotrypsin, but not by RDE or trypsin: it appears to be different from the erythrocyte receptor for myxoviruses and is probably a protein[3].

In 1962 we isolated from a rectal swab of a child in Ossi (Sardinia) a strain of Coxsackie *B* 5 virus (*SS* 31 strain) with an ability to haemagglutinate human erythrocytes[4]. In this it was similar to that of other strains of Coxsackie *B* 5 virus previously isolated by other authors[5,6].

Propagation in HeLa cell cultures of this strain of Coxsackie *B* 5 virus makes its haemagglutinating capacity disappear after the first or second passage, as was observed for haemagglutinating strains of ECHO viruses, types 3, 7, 11, 12, 19 (refs. 7, 8), and, to a lesser degree, for Coxsackie *A* 21 virus (Coe)[9].

A suspension of Coxsackie *B* 5 virus, *SS* 31 strain, in veronal buffer at *p*H 7·2, with a haemagglutinating titre of 1 : 64, was incubated 1 h at 37° C with: (*a*) HeLa cell medium (Eagle's, Hanks's and 5 per cent calf serum solutions), kept in contact with HeLa cells for 5 days; (*b*) control medium (Eagle's, Hanks's, and 5 per cent calf serum solutions), not incubated with HeLa cells; (*c*) HeLa cell monolayers washed twice with Hanks's solution.

Haemagglutinins (HA) were not found (titre < 1 : 2) except in the virus sample which was incubated with HeLa cell medium. HA titre was unchanged after incubation with the control medium and decreased only slightly after contact for 1 h with HeLa cells. In the HeLa cell medium, therefore, there is a factor which inhibits the haemagglutinins of Coxsackie *B* 5/*SS* 31 virus: this factor will here be referred to as 'AHAF' (anti-haemagglutinating factor).

AHAF withstood rapid freezing and thawing five times, heating at 56° C for 30 min, incubation at *p*H 2 and *p*H 12 for 6 h at 37° C. Heating at 100° C for 30 min, on the other hand, rendered it completely inactive.

The effect on AHAF of some chemical compounds and enzymes was investigated: neither ethyl ether nor merthiolate (1 : 10,000) altered its titre, but trifluorotrichlorethane and potassium periodate (5 mg/ml.) clearly decreased its titre; trypsin (1 mg trypsin 1 : 250 Difco/ml., for 6 h at 37° C and at *p*H 7·4) and pepsin (1 mg crystalline pepsin 1 : 60,000 Sigma/ml. for 6 h at 37° C and *p*H 2) brought about the complete disappearance of AHAF.

AHAF is probably a proteic substance perhaps related to human erythrocyte receptors for ECHO viruses. It behaves in a similar fashion to the haemagglutinin inhibitors for Coxsackie *A* 21 (Coe)[9].

Changes in the AHAF-level in the HeLa cell medium (Eagle and Hanks's solutions) were investigated, correlating them to incubation times at 37° C and to the percentage of calf serum in the medium (Table 1). For this purpose, the reagents (which had been diluted in a veronal buffer at *p*H 7·2) were used in the following ratios: (*a*) haemagglutinating virus (Coxsackie *B* 5/*SS* 31), 0·25 ml. 25 HA units; (*b*) HA inhibitor (AHAF), 0·25 ml.; (*c*) 1 per cent suspension of human erythrocytes, 0·12 ml.

HA and AHAF were incubated 1 h at + 37° C and then the suspension of erythrocytes was added: the final reading was made after 2 h incubation at room temperature. AHAF titres were expressed as an inverse ratio of the highest dilution of the medium which inhibits 25 HA units of virus.

Small quantities of an inhibitor were also found to be present in the medium, which contained 10 per cent calf serum before its use with HeLa cells, but they did not vary during incubation at 37° C; on the other hand, it would seem that (within the limits of the sensitivity of the method used) in neither the media with 5 per cent serum nor in the media devoid of calf serum was inhibitor present before their use with HeLa cells.

AHAF clearly increased in HeLa cell cultures from the second to the fifth day of incubation; it also reached moderate levels in HeLa cell cultures devoid of serum, before cell destruction.

This experiment shows that AHAF originates from prolonged contact between the medium and HeLa cells. The presence of proteins in HeLa cell medium does not appear necessary for AHAF production. This could be explained either by the fact that AHAF is a substance produced by HeLa cells and released in the medium, or by the fact that it originates from a modification of the medium components through the action of HeLa cells.

Repeated sub-cultures of Coxsackie *B* 5 virus, *SS* 31 strain, in primary monkey kidney (MK) cells and in newborn mice did not affect its haemagglutinating ability. On the contrary, ten passages of this virus in HeLa cell cultures brought about the irreversible loss of the haemagglutinating capacity, as has already been observed with ECHO virus type 19 (ref. 10): the haemagglutinating capacity of Coxsackie *B* 5 virus/*SS* 31 was not restored even after twenty subsequent passages in primary MK cells.

Acting on the hypothesis that during the propagation in HeLa cell cultures a selection of viral non-haemagglutinating particles (HA−), in comparison with haemagglutinating ones (HA+), might occur, the ratio of HA+ to HA− particles was checked in the original virus sample (sixth MK passage) and in the first four passages in HeLa cells.

For this purpose the material from individual viral plaques, obtained in MK cell cultures with agar overlay, was inoculated in MK cell tubes and the presence or absence of haemagglutinins was determined in the sample of virus resulting from each individual plaque. The results are set forth in Table 2.

In the serial sub-cultures of the virus in HeLa cells, first the HA− particles began to appear and then their titre quickly increased, whereas the HA+ particles were less than a twentieth of all the infectious viral particles present in the sample by the fourth passage.

Table 1. VARIATION OF AHAF TITRES* IN HELA CELL MEDIUM CORRELATED TO INCUBATION TIME AT + 37° C AND TO THE PERCENTAGE OF CALF SERUM IN THE MEDIUM

Incubation time (days)	Kolle 1 5% calf serum	Kolle 2 10% calf serum	Kolle 3 no calf serum	Kolle 4 control without HeLa cells 10% calf serum
0	0	1	0	1

12	8	16	—	1
15	8	16	—	1
17	8	16	—	1
20	8	16	—	1
22	16	32	—	0

* Titre expressed as the reciprocal of the highest dilution showing haemagglutination inhibition of 25 HA units of virus.
† After 7 days' incubation the HeLa cell monolayer was destroyed.

Table 2. BEHAVIOUR OF HAEMAGGLUTINATING CAPACITY OF COXSACKIE *B* 5 VIRUS AND OF RATIO OF HA+ TO HA− PARTICLES AFTER ADAPTATION OF THE VIRUS TO HELA CELLS

Passage history of Cox. *B5/SS* 31	Age of cell cultures at the inoculation point (days)	Haemagglutinating titre: In the material of each HeLa passage	Haemagglutinating titre: After a further passage in MK cells	Studies of individual plaques: No. of plaques examined	Studies of individual plaques: Ratio of HA+ to HA− particles
MK 6		64	64	30	30 : 0
MK 6/HeLa 1	2	<2	128	36	35 : 1
MK 6/HeLa 2	4	<2	32	30	5 : 25
MK 6/HeLa 3	1	<2	16	30	5 : 25
MK 6/HeLa 4	7	<2	<2	20	0 : 20
MK 6/HeLa 5–9	1–5	<2	<2	—	—
MK 6/HeLa 10	3	<2	<2	30	0 : 30
MK 6/HeLa 10/ MK 1–20	—	<2	<2	—	—

From the data set out in Table 2 it can be deduced that the selective pressure which yielded the numerical reduction of HA+ particles in HeLa cell cultures ranged from 1 to 175 times in the individual viral sub-cultures, and showed a positive correlation with the age of cell cultures, expressed as days from the last change of medium, at the time of inoculation. For example, in the second passage in HeLa cells, at the time of inoculation, the medium was 4 days old and an increase of 175 times was demonstrated in the ratio of HA− to HA+ particles; in the third passage in HeLa cells, at the time of inoculation, the medium had just been replaced with a fresh one and on this occasion the relative increase in number of the HA− particles was absent or irrelevant.

Since all thirty plaques of the original sample of virus (MK 6) examined contained HA+ particles, this sample was subjected three times to incubation with human erythrocytes group O at +4° C, in the attempt to adsorb the HA+ virus particles and to enrich the HA− particles which might be present. Packed red cells were added to the virus suspension at a volumetric ratio of 0·2 ml. to 1·5 ml.; the incubation period each time was 1 h, and afterwards the decrease of the virus titre and the ratio of the HA+ to HA− particles was determined in the supernatant. As a control the non-haemagglutinating variant of the same viral strain (MK 6/HeLa 10/MK 6 passage of Coxsackie *B* 5 virus, *SS* 31 strain) was subjected to the same process; this variant had been purified by plaque method in agar-overlay cultures and contained only HA− particles.

Table 3. Adsorption on Human Erythrocytes of the following Samples of Coxsackie *B*5:
(*a*) MK 6 passage; (*b*) MK 6/HeLa 10/MK 6 passage. The former contains haemagglutinins, the latter is devoid of them

Passage history of the virus	Presence of haemagglutinins	Titre in P F U /ml. before adsorption (x)	Titre in P.F.U./ml. after adsorption (y)	Ratio of the titres $\left(\frac{x}{y}\right)$	Ratio of HA+ to HA− particles after adsorption
MK 6	+	$3{\cdot}25 \times 10^7$	$2{\cdot}9 \times 10^4$	$1{\cdot}12 \times 10^3$	20·11
MK 6/He La 10/MK6	−	$2{\cdot}15 \times 10^7$	$3{\cdot}8 \times 10^7$	0·57	0 : 30

From Table 3 it can be deduced that the HA+ particles were adsorbed to erythrocytes, whereas the HA− ones were not adsorbed at all. The ratio of virus HA+ to HA− particles in the MK 6 virus sample can be estimated as 3,155 : 1.

These experiments indicate that HeLa cell cultures affect a population of Coxsackie *B* 5 virus particles, in that they promote the rapid selection of the non-haemagglutinating particles, which are very rare in the original samples as compared with the haemagglutinating ones.

The mechanism of action of the factor which inhibits the infectiousness of HA+ particles of Coxsackie *B* 5 virus, *SS* 31 strain, remained unknown; other questions which remain to be answered are whether this factor is the same as the anti-haemagglutinating factor (AHAF) demonstrated in HeLa cell medium or whether it must be differentiated from AHAF.

Isolation and Identification of Poliovirus from a Clinical Specimen

At present, the isolation and identification of viruses from clinical specimens is a slow, expensive and tedious process[1,2]. Modifying a technique previously described[3], we were able to isolate and identify in three rapid and relatively simple steps a prototype virus from a sample of faeces seeded with a known quantity of polio virus.

DEAE 'Sephadex' *A*-25 medium-grade columns were prepared and used as previously described[3]. All columns were 14 × 1·2 cm. The elution of virus from all columns was accomplished with M/15 phosphate buffer (*p*H 7·5) at a rate of 1 ml. per min. The first eluate in all experiments was 3 ml.; all others were 1 ml. quantities. Protein content of the eluates was determined by the method of Lowry[4]. The prototype virus used was the avirulent Sabin type I polio-virus. Virus assay was accomplished by plaque titration on HeLa cell monolayers propagated in 2*X* Eagle's basal medium supplemented with 10 per cent calf serum and 15 per cent tryptose phosphate. Antibody against this virus, prepared in rabbits[5], was tagged with fluorescein isothiocyanate[6]. The virus-antibody complex was dissociated by lowering the *p*H with an acid buffer[7].

1 ml. of a 1 : 10 dilution of fluorescein-tagged type I poliovirus antiserum was added to three columns. A fourth column served as the control and received no antiserum. 0·5 ml. of Sabin type I poliovirus having a titre of 5×10^7 P.F.U./ml. was added to these columns. The virus was in contact with the antibody for various time intervals prior to elution with buffer. The 16-h antigen–antibody association was performed at 4° C, whereas the 1 and 2 h reactions were carried out at room temperature. The above time intervals were followed, elution was accomplished with phosphate buffer, and the viral content of the eluate was determined.

Neutralization of poliovirus by tagged antibody suspended in a column. Fluorescein-tagged, immune serum (of any type), when added to a column, is held in that position. This is in contrast to untagged, immune serum which is rapidly eluted with phosphate buffer.

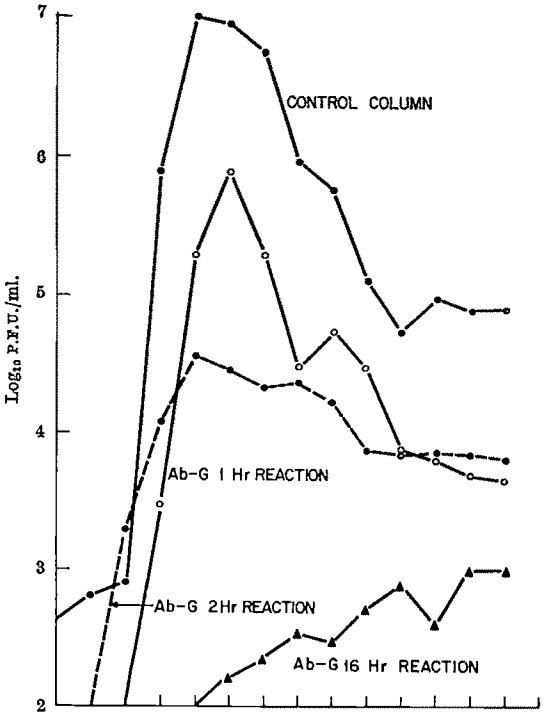

Fig. 1. Type I poliovirus retention by fluorescein-labelled type I antiserum in relation to the time interval of antigen-antibody association. Ab, antibody; G, antigen

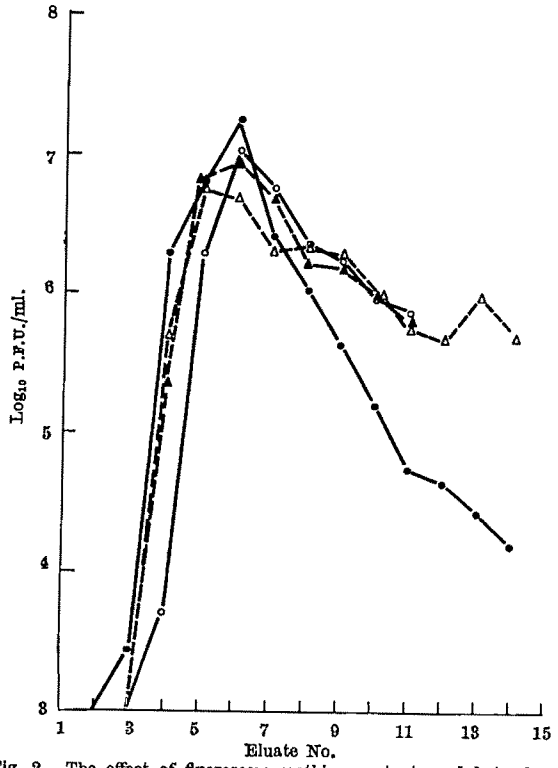

Fig. 2. The effect of fluorescein isothiocyanate tagged heterologous antiserum on the movement of Type I poliovirus in an *A*-25 column. ●—●, Control column; ○—○, Ab-G 1 h reaction; ▲—▲, Ab-G 2 h reaction; △—△, Ab-G 16 h reaction. Ab, anti-guinea-pig antibody; G, antigen

Results, as seen in Fig. 1, indicate that approximately 90 per cent of the virus failed to be eluted after 1 h of fluorescein-tagged type I poliovirus antiserum : type I poliovirus association; by 2 h, more than 99 per cent of the virus was retained; by 16 h, essentially all the virus was bound to the column.

Specificity of reaction. There was the possibility, of course, that the virus was not neutralized by specific antibody, but was physically retained, indicating a non-specific reaction.

The same procedure as in the foregoing experiment was followed except that fluorescein-tagged rabbit anti-guinea-pig antiserum was used instead of fluorescein-tagged type I poliovirus antiserum. Results, as seen in Fig. 2, demonstrated that almost all the type I poliovirus was recovered from each column. It can thus be concluded that the virus was not physically retained.

To test the specificity of the reaction, a column was loaded with 1 ml. of a 1 : 10 dilution of fluorescein-tagged polio type III antibody (kindly supplied by Dr. M. H. Hatch); 0·5 ml. type I poliovirus having a titre of 8×10^7 P.F.U./ml. was added and allowed to react for 2 h before eluting. The results, as seen in Table 1, are representative of several experiments and demonstrate that approximately 85 per cent of the virus was recovered. It can be concluded from these results that the column neutralization reaction is highly specific.

Table 1. Specificity of the Neutralization Reaction Sabin Type I Poliovirus reacted against Fluorescein-tagged Type III Poliovirus Antiserum

Eluate No.	Virus (P.F.U./ml.)

Table 3. Recovery of Antiserum Neutralized Poliovirus from Column by Acid Buffer Dissociation

Portion of column dissociated	Virus P.F.U./ml.
Fluorescein labelled Type I antiserum Top (2 cm)	$2{\cdot}0 \times 10^4$
Middle (6·7 cm)	0

Isolation of poliovirus from faecal material. Type I poliovirus (8×10^6 P.F.U.) was added to 2 ml. of a heavy suspension of monkey faeces. After vigorous mixing, the suspension was centrifuged at 1,200 r.p.m. for 15 min. 1 ml. of the supernate was then added to a column which had previously been loaded with fluorescein-tagged type I poliovirus antiserum as above; an equal volume was added to a control column not containing the poliovirus antiserum. After 2 h, the columns were eluted. Eluates were analysed for protein and virus content.

The results in Table 2 show that less than 2 per cent of the virus was recovered from the column containing the fluorescein-tagged antiserum while about 80 per cent of the virus was recovered from the control column. The protein analysis similarly demonstrated the capacity of the column to provide a 'clean' preparation. One may conclude from these data that the poliovirus from the faeces sample had been specifically neutralized.

The fluorescein-tagged antiserum was removed from the column and the virus was dissociated with acid buffer. As a control, samples from the same column not associated with the antibody band were treated in a similar manner and assayed for virus.

The results, in Table 3, indicate that virus was present only at the site of antiserum localization.

It was apparent that this technique has application for the isolation and identification of certain viral agents. Subject to refinement of antigen–antibody dissociation techniques, viruses present in quantities commensurate with those found in a viral disease should be detectable. It is conceivable that by proper positioning of a variety of fluorescein-labelled antisera on a DEAE 'Sephadex' *A*-25 column, differential diagnosis could be achieved. The indirect fluorescent antibody technique can be utilized for this procedure[8], thereby eliminating the requirement for specific fluorescein-tagged antiserum. This method has further application in removing extraneous material from clinical specimens which might otherwise result in non-specific cytopathogenic responses in tissue cultures.

CYTOLOGY

Chromosomal Constitution of Human Endometrium

It is generally assumed that there is a diploid number of chromosomes in nearly all human somatic cells. That this is not true for the endometrium was first reported by Timonen[1] in 1950. He found chromosome numbers ranging from 4 to 104 in 1,000 cells of human endometrium. Manna[2] observed similar aneuploidy in this tissue. Sachs[3], on the other hand, found no variation from the normal diploid number in either human or rat endometrium. Walker and Boothroyd[4], although they found chromosome counts ranging from 42 to 56, believed that the apparent aneuploidy was caused by the methods used, and suggested that Timonen's results were similar artefacts produced by the technique. Since all these investigators used squash preparations without previous hypotonic treatment, it is quite possible that in some cases accurate counts were not possible or that fragmentation occurred. Furthermore, the human diploid chromosome number was, at that time, believed to be 48, and this erroneous belief may also have biased the results obtained. Although new methods were introduced into human cytogenetics and the quality of the preparations was greatly improved, the question of aneuploidy in the endometrium has remained unanswered. In 1958, Tjio and Puck[5] reported that they had found only diploid and some tetraploid cells in endometrium grown in tissue culture. Takemura[6], however, found that of 109 cells only 51·4 per cent had 46 chromosomes, the chromosome counts in the others ranging from 33 to 95.

The purpose of our investigation was to establish the chromosomal pattern of the human endometrium as a part of a study concerned with reproductive disorders. The endometrium was obtained by biopsy from 28 women of child-bearing age, including seven normals, 14 with a history of sterility and seven with a history of repeated abortions. Of these, seven represented the proliferative and 21 the secretory phase of the menstrual cycle. The tissue was cultured *in vitro* after a modification of the method described by Chu and Giles[7]. In most cases primary cultures were used for chromosome preparations. Colchicine in a final concentration of 2–3 μg/ml. was added to the cultures 16 h before harvesting. The cultures were then trypsinized, and the cells were treated with 20 per cent Hanks's balanced salt solution in distilled water for 20 min, fixed, allowed to air-dry on slides, and stained with dilute Giemsa stain. All metaphase spreads of adequate technical quality were counted, and every attempt was made to exclude broken cells.

Chromosomes were counted in a total of 449 mitoses, with the counts ranging from 17 to 103 chromosomes per cell. 119 of the cells counted had the normal number of 46 chromosomes. The distribution of the counts is given in Table 1. Aneuploidy was found in every culture. No chromosomes with abnormal morphology were observed.

CALCUTTA

These results support the findings of high degrees of aneuploidy in the human endometrium. The chromosome counts are similar to those obtained by the earlier workers, all of whom used the direct squash method without tissue culture in their investigations. This indicates that the conditions of *in vitro* growth, as used in this work, do not significantly alter the chromosome complement or result in selective growth of cells with a given karyotype. Similarly, the only difference between our preparations from primary cultures and sub-cultures has been a higher mitotic rate in the latter.

It seems clear that there is aneuploidy in the human endometrium, and that aneuploidy is, indeed, normal for this particular tissue. Since aneuploidy is believed to be the result of certain abnormalities of either meiosis or mitosis, and since endometrium is a very rapidly growing tissue, it is likely that the high degree of aneuploidy observed in the endometrium reflects in some way the normal growth and development of the tissue itself. If this is true then the degree of aneuploidy would be expected to vary with the menstrual cycle. Our preliminary results suggest that this is, indeed, the case.

SOIL SCIENCE

Influence of Ionic Phosphate Diffusion in the Soil on the Growth of *Hormidium flaccidum*

A knowledge of the ionic mobility of the essential plant nutrients in the soil is of considerable importance in determining the method and effect of particular fertilizer programmes in the eventual crop growth. Scott Russell and Newbould[1] and Schofield[2] have indicated the importance of this and the difficulties which lie behind the investigation of it. Calcium and phosphate would, for example, directly enter into exchange reactions in the soil so that the rate of ionic mobility would become limited by the degree of this interaction. Newbould[1] showed that calcium could reach a state of equilibrium in the exchange system of the soil within seven days; Fried and Shapiro[3] elaborated the factors affecting the mobility of ions by demonstrating that both the water movement in the soil, and the addition of inert material to the soil, would accelerate the diffusion of ions. Most of this work has been carried out using labelled isotopes. However, Scott Russell[1] has indicated that, even using these techniques, the knowledge of the mechanisms of diffusion was still meagre.

During an investigation of a new method of soil bioassay using algae I found[4] that *Hormidium flaccidum*, when impregnated into nutrient-deficient soils, would give, by way of its growth, indication of the distance and of the rate at which nutrient ions may diffuse in the soil.

In the method used, 10 g of dried, sieved soil with a known phosphate deficiency was added to a sterile standard bacteriological dish. An inoculum containing 5×10^5 cells/ml. of *Hormidium flaccidum* was mixed with the soil until it became saturated to a mud-like paste. To encourage algal growth throughout the soil, the soil was then incubated at 25° ± 1° C for 7 days at an even

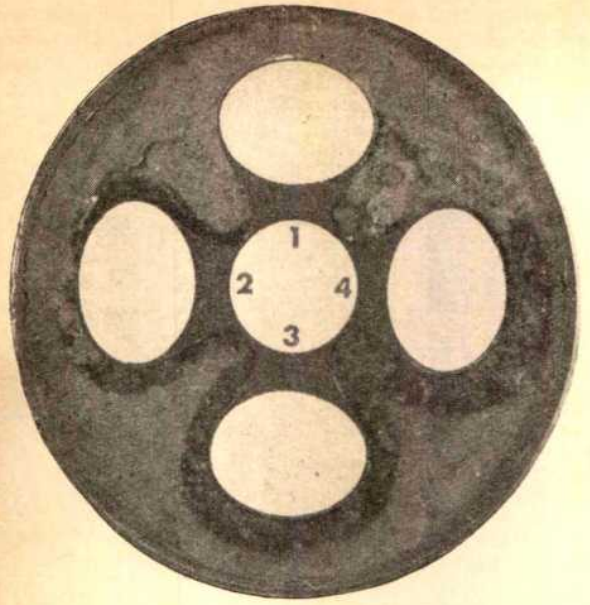

Fig. 1. Enhanced algal growth around impregnated zones on soil 35 (*R*)

illumination of 600 m-candles using 'daylight' fluorescent tubes. At the end of the 7 days, a paper rosette with four appendages cut from Whatman No. 542 double acid-washed filter paper was placed on the soil. Each of these appendages was impregnated with a different concentration of sodium dihydrogen phosphate (mg/sq. cm): zone 1, 0·00; zone 2, 0·005; zone 3, 0·0109; zone 4, 0·0219. The soil plate was now incubated for a further 6 days at 25° ± 1° C and 600 m-candles. During this period, the phosphate ions diffused out into the soil and this enhanced the algal growth around each of the treated disks (Fig. 1). At the end of incubation, the distance was measured between the edge of each of the impregnated zones and the end of the zone of enhanced algal growth. Three soil samples were used in this investigation which had been obtained from the Food and Agriculture Organization Soil Fertility Project, Teheran, Persia, through the courtesy of Dr. G. F. Hauser, the project manager. The results are recorded in Table 1.

Table 1. Distance (cm) of Phosphate Diffusion through the Soil Samples in 6 Days as shown by Enhanced Algal Growth

Zone No.:	1	2	3	4
Soil sample 26 (*SB*)	0·00	0·28	0·77	1·08
Soil sample 35 (*R*)	0·00	0·25	0·41	0·56
Soil sample 44 (*R*)	0·00	0·46	0·60	0·61
NaH_2PO_4 conc. (mg/sq.cm)	0·00	0·0051	0·0109	0·0219

In all these soils, as the concentration of phosphate in the impregnated zones increased so the diameter of enhanced algal growth increased. None of the non-impregnated zones showed any stimulated growth. The rate of phosphate diffusion varied considerably both in extent and degree for the soils used. Samples 26 (*SB*) and 35 (*R*) showed a very similar initial diffusion rate around zone 2, but after this the growth areas became far wider in the former. This would suggest that the phosphate ion may be able to diffuse more easily through this soil, due, perhaps, to the presence of a higher proportion of inert material in the soil. Soil sample 44 (*R*) initially showed a broader algal growth area, but this only increased by 0·15 cm at the highest phosphate concentration. It is probable that the phosphate diffused more quickly through this soil, due to the fact that it had a more open texture, but then became rapidly bound into the exchange complex.

The use of algae to indicate the travel of plant nutritive ions through the soil has some disadvantages. First, the algae utilize some of the ions and so reduce the overall concentration effect. Secondly, the algae only grow in light, and this limits growth to the surface, thus surface mobility can only be studied. Thirdly, the soil must be deficient in the ion which is to be studied. Despite these disadvantages, the method may provide a simple way of studying the mobility of ions in the soil under limited conditions. Work is at present in progress to investigate these conditions.

I thank Dr. G. F. Hauser for provision of soil samples.

PSYCHOLOGY

Optical Illusions

Recent articles[1–3] in *Nature* have discussed the explanation of optical illusions and, in particular, Gregory's theory of constancy scaling. According to this theory, illusions are produced in situations where there is an inappropriate activation of a constancy scaling mechanism produced either by certain features of the two-dimensional visual pattern which normally suggests depth (primary scaling), or by apparent distance (secondary scaling). This communication presents some critical comments on this type of explanation as applied inclusively to all the optical illusions mentioned.

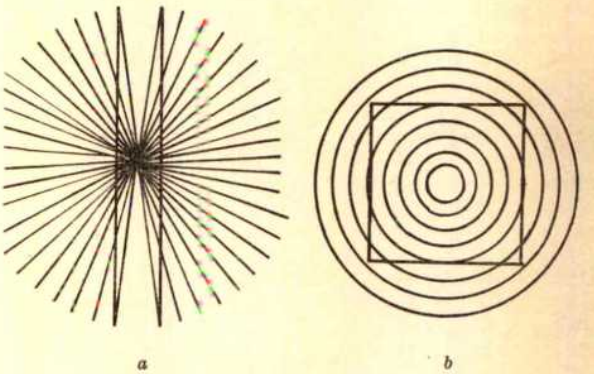

Fig. 1. Two optical illusions in which the perspective sense is the same but opposite distortions are produced

With regard to primary scaling, Gregory states that the parts of figures corresponding to distant objects are expanded and the parts corresponding to nearer objects are reduced. He also states that "the generalization seems to hold for all the visual illusions thought of in this way". In two of his own figures, however, there appears to be a discrepancy. Comparing the two illusions (Fig. 1*a* and *b*) it is clear that the perspective sense is the same in each. In *a* the centre to which the lines converge corresponds to the most distant part, as does the smallest of the concentric circles in *b*. Yet the vertical lines are distorted in opposite directions in the two cases. Of course, it would be possible, though unusual, to regard the smallest circle in *b* as the nearest part of a depth configuration, for

Fig. 2. The slight apparent bending of the horizontal line in the figure obeys the rule of the acute angles (see text). As in all such cases it is the single line which is distorted, not the repetitive stripes. This figure also contains the key configuration in Gregory's Necker cube and shows that the cube itself is unnecessary

example, as the top of a cone. To do this, however, is to make a quite arbitrary designation of the perspective sense, and the distance explanation then loses any predictive value.

A general rule which applies to all cases of figural distortion on a background field is that acute angles are perceptually enlarged (Fig. 2). This has been discussed by previous authors[4]. This rule has the merit of applying in the two cases in Fig. 1 and, in addition, since distortion is related to the acuteness of the angle of intersection, it predicts the curved distortion in these figures and the linear distortions in illusions such as the Zöllner. Unfortunately, in the majority of cases, the constancy scaling hypothesis and this angle rule for distortion predict exactly the same effects, so that it is difficult to distinguish the two experimentally. Indeed, this angular distortion is basic to Tausch's explanation of many illusions[5]. He postulates that lines forming an acute angle represent a right angle in perspective view and this cue for perspective produces the distortion, or in Gregory's terms, sets the scaling. At this extreme, Tausch's hypothesis is not useful since it is, in fact, not disprovable. Any angle can be regarded as the perspective view of a right angle, and, consequently, any pattern containing line intersections can be held to possess depth cues. The fact that the distortions observed in the illusion figures operate in the appropriate direction does not in any sense prove that they are due to the interpretation of an acute angle as a right angle. The same criticism applies to the interpretation of the bending of the line in Gregory's Necker cube figure. The bending of the line is, of course, not dependent on the presence of a Necker cube, it occurs in other configurations also (Fig. 2). All such configurations are subject to the previously mentioned ambiguities of interpretation. In further support of his depth hypothesis, Gregory reports that, in the case of the illusions where figures are distorted by a background, the illusion disappears when the affected lines are displaced in depth from the background in a stereoscope. One can produce this displacement more simply by etching the main long lines on a 'Perspex' sheet and viewing the background pattern through this at a distance (for example, at 50 cm). The Zöllner and Hering illusions are still strikingly present in such conditions. A final interesting point is that the Zöllner illusion is still present if the whole display is in three dimensions, with the pattern on the floor of a normal daylit room and the main lines extending away from the observer over a distance of 4 m. The distortion produced by the configuration thus persists even in the presence of real perceived depth. The only concrete evidence for the constancy scaling hypothesis in the context of the illusions is Gregory's experiment relating measurements of apparent distance to the size of the illusion. The correlation of 0·9 which he quotes for the Müller–Lyer is extremely convincing. In view of this, but acknowledging some of the points already mentioned, it is possible to suggest that illusions like the Müller–Lyer and Ponzo's illusion are different types of illusion from the distortion of figures on patterned fields. Such distortions remind one forcibly of some of the phenomena described by McKay[6], in particular his finding that such repetitive fields impose an orderly movement on a random noise pattern, such that the dots appear to move at right angles to the lines of the pattern. His interpretation of this and applied phenomena in terms of the satiation of certain direction analysers and of sampling of the visual field may be the correct interpretation of the distortion illusions. Certainly none of the known facts concerning these illusions appear to controvert this.

[6] McKay, D. M., in *Sensory Communication*, edit. by Rosenblith (Wiley, New York, 1961).

I would disagree with Mr. Wallace that Figs. 1*a* and 1*b* have the same perspective sense. On my view there are gradients of expansion along each of the converging lines of 1*a*. This expansion is due to the converging perspective of these lines, so that any feature near the middle of this figure should be, and is, expanded. This gives the outward bowing of the vertical line, since the expansion is greater where these lines are near the centre of the figure. Fig. 1*b* is less obvious. If the arrangement of equally spaced circles is viewed as a luminous figure, with a single eye, to prevent the competing information that it is in fact flat, it appears flat. If, however, the spacing of the circles is non-uniform, then it will be seen as a tunnel or a cone, depending on whether the spacing increases or decreases outward from the centre. In other words, the depth of the background figure depends on the spacing of the circles, not the circles themselves.

What we must consider is why primary scaling should be set by the arcs of the circles touching, or nearly touching, the straight lines. Their distortion is compatible with the form of the Müller–Lyer illusion having curved ends. An ingoing curve produces shrinking, as does the more familiar ingoing corner. It seems that, in this Orbisson figure, the ingoing arcs produce local shrinking in the same way, giving the observed inward bowing of the superimposed lines. My hypothesis does not lose predictive power through arbitrariness, for the local depth effect can be directly measured in this, as in other, cases.

In pointing out that a line straight across a Necker cube appears bent, I realized that the whole of the Necker figure is not necessary to produce the bending. The point of using a complete Necker cube, rather than just a corner, was to show, using the reversal properties of the figure as a whole, that the bending is in the same direction whether this corner is seen in inward or outward depth. It is a crucial observation to distinguish between primary and secondary constancy. Wallace evidently fails to see the significance of this point, and his Fig. 2 does not add anything to the discussion.

With regard to illusions in binocular perception: this is very complicated, and exactly why they sometimes disappear and sometimes do not remains to be worked out. I would not agree that reference to direction analysers is helpful in explaining these illusions, for we know too little of their properties. In any event, 'satiation' can scarcely be involved, for this implies a time course; but these illusions are seen instantaneously and do not increase with prolonged viewing. The particular strength of the misplaced constancy theory is that it clearly relates well-established perceptual phenomena and does not require special or untestable assumptions.

Cambridge.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, January 17

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 2.30 p.m. and 5 p.m.—Colloquium on "Active Filters".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Prof. A. J. Birch: "Some Natural Anti-Fungal Agents".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5 30 p.m —Dr. D. R. Laurence: "Drug Introduction, Evaluation and Safety" (Inaugural Lecture).*

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. M. W. Thring: "The Present and Future Uses of Machinery". (First of three Cantor Lectures on "The Place of the Technologist in Modern Society".)

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Prof. M. G. Say: "Unusual Electrical Machines".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Major P. G. Boxall: "Island of Bliss".

Tuesday, January 18

INSTITUTION OF CHEMICAL ENGINEERS, SOUTH EASTERN BRANCH (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 4.30 p.m. —Branch Annual General Meeting, followed by Mr. F. E. Warner: "The Professional Chemical Engineer and the Council of Engineering Institutions".

PLASTICS INSTITUTE, LONDON SECTION ENGINEERING SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 5 p.m.—Symposium on "Extrusion Plant".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Colloquium on "Human Operator Studies".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p m.—Dr. J. F. Loutit, F R.S.: "Strontium-90 and Leukaemia". (Second of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

INSTITUTION OF MECHANICAL ENGINEERS, PROCESS ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Pressure Vessels and the Factories Act 1961".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the Heavy Organic Chemicals Group, at 14 Belgrave Square, London, S W.1), at 6 p.m.—Prof. V. M. Clark "Is Organic Chemistry Dead?"

Wednesday, January 19

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p m —Mr. C. B. Winsten and Miss F Savigear. "The Use of Rooms and the Use of Land for Housing".

UNIVERSITY OF LONDON (at the Royal Free Hospital School of Medicine, 8 Hunter Street, Brunswick Square, London, W.C.1), at 5.30 p.m.—Prof. M. G. Larrabee (Johns Hopkins University) "The Metabolism of an Excised Sympathetic Ganglion at Rest and in Action".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 6 p.m.—Mr. D. Reaney: "Industrial Applications of Electroluminescence"

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, RADAR GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m —Mr J. Croney: "Improved Radar Visibility of Small Targets in Sea Clutter (through Decorrelation by a Rapidly Rotating Antenna)".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Sir Edmund Hirst, C B E , F.R S.: "The Role of Sugars as Energy Reserves in Nature" (Sir William Jackson Pope Memorial Lecture).

INSTITUTE OF INFORMATION SCIENTISTS (at the Whitehall Hotel, Bloomsbury Square, London, W.C.1), at 6.15 p.m.—Mr. J. B. Reed: "Spotlight on Systems of Abstracts".

SOCIETY FOR ANALYTICAL CHEMISTRY, MICROCHEMICAL METHODS GROUP (joint meeting with the Association of Clinical Biochemists, at "The Feathers", Tudor Street, London, E C 4), at 6 30 p m.—Discussion on "The Instrumental Measurement of Coloured Solutions in the Range of 200–700 mμ".

SOCIETY OF DYERS AND COLOURISTS (at the School of Pharmacy, University of London, Brunswick Square, London, W C.1), at 6.30 p.m —Sir Robert Robinson, O.M , F.R.S.: "Colour in Flowers" (Thirteenth London Lecture).*

Thursday, January 20

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 1.30 p.m.—Mr. Patric Dickinson: "Computer versus Creator".*

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. O W. Nicolls, Dr. D M J. Provan, Prof. M. M. Cole and Dr. J. S. Tooms: "Geobotany and Geochemistry in Mineral Exploration in the Dugald River Area, Cloncurry District, Australia", Mr. V. E. Clifton: "The Condensation in Stages of Metal from Vertical Zinc Retorts".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m —Mr. A. D Pearson: "Lemmings—Fact and Fantasy"; Dr. C. B. Cox: "The Origin of the Modern Amphibia".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. P. M. Cohn: "Determinants".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C 2), at 5.30 p.m.—Mr. E. R. Davies, Mr. R. J. Gamble and Mr. J. B. Silleto: "Electric Process Heating for the U.K.A.E.A. Works".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. D. G. ff Edward: "Mycoplasma and their Role in Human Disease". (Third of fifteen lectures on "The Scientific Basis of Medicine", organized by the British Postgraduate Medical Federation.)*

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Meeting on "The Weathering of Road Tar". Dr. E. D. Tingle and Mr. E. H. Green: "Mechanism of Changes in Tars in Road Surfacings and their Relation to Laboratory Tests": Mr. W. G. Wilman and Mr. K. D. Bartle: "Chemical Changes in Road Tars in Service".

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. H. A. K. Rowlands: "Anaemia in Dar-es-Salaam and Methods for Its Investigation", followed by a Discussion.

Thursday, January 20—Friday, January 21

INSTITUTION OF MECHANICAL ENGINEERS, INTERNAL COMBUSTION ENGINES GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1)—Symposium on "Accuracy of Electronic Measurements in Internal Combustion Engine Development".

Friday, January 21

INSTITUTE OF NAVIGATION (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 5.30 p.m.—Mr. C. Powell and Mr. A. Woods: "Loran C".

UNIVERSITY OF LONDON (in the Gustave Tuck Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m —Prof. Saunders MacLane (University of Chicago): "Universal Elements in Algebra".*

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), at 5 30 p.m.—Mr. N. Burak: "Chemicals for Improving Flow Properties of Powders".

ROYAL INSTITUTION (at 21 Albermarle Street, London, W.1), at 9 p.m.— Prof. M. J. Lighthill, F.R.S.: "Waves in Fluids".

Saturday, January 22

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3 30 p.m.—Dr. W. J. Rees: "The Rocky Sea Shore".*

Monday, January 24

INSTITUTE OF ACTUARIES (at Staple Inn, High Holborn, London, W C.1), at 5 p.m.—Sir Paul Chambers, K.B E., C B., C.I.E.: "Problems in Forecasting in the Chemical Industry" (Twelfth Alfred Watson Memorial Lecture).

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5 p.m —Dr. W. N. Aldridge: "Hydrolytic Enzymes and their Inhibitors" (Further lecture on January 31).*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p m.—Dr. H Ahmed, Mr. C. E. Maloney, Mr. J. D. Sankey and Mr. A. H. Beck: "Recent Studies of Dispenser Cathodes".

INSTITUTION OF ELECTEICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5•30 p m.—Colloquium on "Gaseous Insulation".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof M. W. Thring: "Towards a Creative Society: The Philosophy of Technology". (Second of three Cantor Lectures on "The Place of the Technologist in Modern Society".)

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEMONSTRATOR IN GENETICS—The Secretary to the College, Trinity College (University of Dublin), Dublin 2, Republic of Ireland (January 20).

CHAIR OF PHYSICAL CHEMISTRY—The Registrar, The University, Sheffield (January 22).

CHAIR OF THEORETICAL CHEMISTRY—The Registrar, The University, Sheffield (January 22).

LECTURER or ASSISTANT LECTURER (preferably specialized in analysis or topology, or mathematical logic) IN PURE MATHEMATICS—The Registrar, The University, Sheffield (January 22).

LECTURER (with a degree in chemistry and good teaching experience) IN EDUCATION—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 25).

ASSISTANT LECTURER IN PURE MATHEMATICS—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (January 24).

LECTURERS (2) (preferably with research interests in algebra) IN PURE MATHEMATICS; and a LECTURER IN EITHER STATISTICS OR APPLIED MATHEMATICS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Newcastle upon Tyne, 2 (January 28).

RESEARCH ASSISTANT (with a higher degree or equivalent experience) IN THE DEPARTMENT OF MECHANICAL ENGINEERING for a project on flame trap performance—The Secretary, University College, Gower Street, London, W.C.1 (January 30).

CHAIR OF STATISTICS—The Secretary, The University, Aberdeen (January 31).

FELLOW and TUTOR (woman) or a LECTURER (man or woman) IN PHILOSOPHY—The Principal, St. Hugh's College, Oxford (January 31).

LECTURER/ASSISTANT LECTURER IN PHYSICAL CHEMISTRY; and a RESEARCH OFFICER to assist in the operation of and development of programmes for the College's IBM 1620 tape/disc/card system—The Registrar, University College of Wales, Aberystwyth (January 31).

LECTURER IN NUCLEAR PHYSICS and a LECTURER IN THEORETICAL PHYSICS (candidates should have postgraduate experience in high energy physics or theoretical physics)—The Secretary, University of Lancaster, Bailrigg House, Lancaster (January 31).

LECTURER (with special interests in ecology) IN ZOOLOGY—The Registrar, King's College (University of London), Strand, London, W.C.2 (January 31).

READER IN BIOCHEMICAL ENGINEERING; and a LECTURER IN CHEMICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea (February 1).

CHAIR OF THEORETICAL CHEMISTRY—The Deputy Secretary, The University, Southampton (February 4).

SENIOR LECTURER, LECTURER or ASSISTANT LECTURER IN BOTANY at the University of Zambia—The Inter-University Council, 33 Bedford Place, London, W.C 1 (February 4).

LECTURER IN STATISTICS IN THE DEPARTMENT OF APPLIED STATISTICS (formerly the Unit of Biometry)—The Registrar (Room 39, O.R.B.), The University, Reading (February 5).

LECTURER or ASSISTANT LECTURER IN PSYCHOLOGY—The Registrar (Room 39, O.R.B.), The University, Reading (February 5).

DEAN OF THE ROYAL MILITARY COLLEGE OF SCIENCE, Shrivenham, Wiltshire—Ministry of Defence (C.E.2 A.D.), Northumberland House, Northumberland Avenue, London, W C 2 (February 7).

CHAIR OF PSYCHIATRY at the Institute of Psychiatry—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 8).

ASSISTANT LECTURER IN MICROBIOLOGY—The Registrar, The University, Sheffield (February 12).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS (preferably with the degree of Ph D. or equivalent research experience) IN BIOCHEMISTRY, CHEMISTRY, ENGINEERING, PHARMACOLOGY, PHYSICS, or related subjects—The Secretary, The University, Aberdeen (February 12).

READER IN THE PHYSICAL EXAMINATION OF MATERIALS—The Registrar, University Registry, Oxford (February 12).

CHAIR OF PURE MATHEMATICS IN THE DEPARTMENT OF PURE MATHEMATICS AND MATHEMATICAL STATISTICS—The Registrar, University College of South Wales and Monmouthshire, Cardiff (February 15)

CHAIR OF CHEMISTRY at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, February 28).

CHAIR OF PHYSICS at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S W.1 (Hong Kong and London, February 28).

CHIEF PHARMACIST OF THE HOSPITAL and SENIOR LECTURER IN PHARMACY TO THE MEDICAL COLLEGE (combined post)—The Dean of the Medical College, St. Bartholomew's Hospital, London, E.C 1 (February 28).

DIRECTOR (registered member of the veterinary profession and research experience relating to the improvement of health and the control of disease in horses) OF THE ANIMAL HEALTH TRUST'S EQUINE RESEARCH STATION, at Balaton Lodge, Newmarket—The General Secretary, The Animal Health Trust, 14 Ashley Place, London, S.W.1 (February 28).

LECTURER IN THE DEPARTMENT OF MATHEMATICS, University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, February 28).

LECTURER (specially interested in the mathematical techniques of optimization and preferably experience in these topics in an industrial context) IN THE DEPARTMENT OF MATHEMATICS and the DEPARTMENT OF SYSTEMS ENGINEERING (joint appointment)—The Secretary, The University of Lancaster, Bailrigg House, Lancaster (February 28).

READER (preferably actively engaged in research in pure mathematics) IN MATHEMATICS in the School of Physical Science in the University of Adelaide at Bedford Park, South Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, February 28).

CHAIR OF EDUCATION—The Registrar, University Senate House, Bristol, 2.

PHYSICIST or ELECTRONICS DEVELOPMENT ENGINEER (with a good knowledge of nuclear instrumentation and electronics, but previous experience of computers is not essential) to work with the recently installed PDP-7 on-line computer in the Nuclear Physics Laboratory—Prof. K. W. Allen, Nuclear Physics Laboratory, The University, 21 Banbury Road, Oxford

PHYSICISTS FOR FUNDAMENTAL STUDIES—proposed topics gas discharges, plasma diagnostics, electro-luminescence, magnetic materials, dielectrics, microwave and spectroscopic physics over all frequencies—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Cheshire, quoting Ref N/1.

SENIOR PHARMACIST (full or part-time)—The Physician Superintendent, Oakwood Hospital, Maidstone, Kent.

SENIOR RESEARCH OFFICER (biochemist) (male or female, fluent in English, with a good honours degree in biochemistry or chemistry together with at least 10 years postgraduate experience, and preferably an interest or experience in microbiology) at the National Institute for Trypanosomiasis Research, Kaduna, Northern Nigeria—The Crown Agents, M. Dept., 4 Millbank, London, S W.1, quoting Ref. M3F/54445/TA.

S R C. RESEARCH ASSISTANT to work in the field of reactions of co-ordinated ligands—Dr P. J. Staples, Department of Chemical Technology, Bradford Institute of Technology, Bradford, 7, Yorkshire.

TEMPORARY LECTURER or TEMPORARY ASSISTANT LECTURER (pure or applied mathematician) IN THE DEPARTMENT OF MATHEMATICS—The Secretary, University College, Gower Street, London, W C 1

ZOOLOGISTS (M Sc. or Ph.D with research experience, and preferably some knowledge of histology and histochemistry) to participate in experimental multi-disciplinary programmes of basic research in the field of food additive toxicology—The Director, British Industrial Biological Research Association, Woodmansterne Road, Carshalton, Surrey.

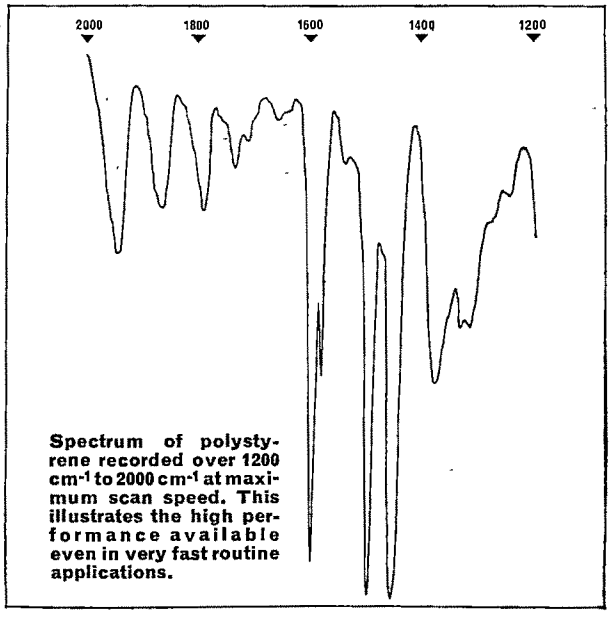
NEW high speed SP200 infrared spectrophotometer



three times faster

The new high speed version of the SP200 provides a complete spectrum (650-5000 wavenumbers) in 200 seconds. The rapid response of the instrument enables spectra to be recorded three times faster than previously.

This brilliantly engineered instrument is ideal for routine chemical analysis. Its well-tried advantages include a flat bed recorder and ball point pen, capable of producing simultaneous carbon copies of spectra. Slit programmes up to ten times the normal energy may be selected. Specially designed accessories, such as the scale expansion unit featured above, are available to increase its versatility.

The SP200 is unrivalled for simplicity and is designed for constant and demanding use. Descriptive literature is available on request.

Spectrum of polystyrene recorded over 1200 cm^{-1} to 2000 cm^{-1} at maximum scan speed. This illustrates the high performance available even in very fast routine applications.

INTENSIVE LIVESTOCK HUSBANDRY

THERE have been innumerable public complaints about intensive livestock husbandry as it has developed in Britain since the Second World War. 'Factory farming', tied as it is to 'agribusiness', is seen as inimical to the normal life of the countryside and destructive of some natural virtues necessary to our society. This view is not just an inevitable protest against progress, for this form of farming is also suspected of being economically inefficient, surviving only on subsidies and on imported grains and concentrates. Its products are mistrusted on medical grounds, and they are often found to be tasteless, or even obnoxious, and a separate industry has come into being to supply the natural, unadulterated items in their place; but at a premium. The subject clearly has strong emotional overtones, and these are most obvious when its techniques are attacked as being unnecessarily cruel, and detrimental to the welfare of the animals being exploited. These issues are interrelated, and it is to be regretted that the Brambell Committee, which has just reported *, should have been appointed to enquire only into the welfare of animals kept intensively. The roles of subsidies, of imports of feeding-stuffs, the use of food additives and drugs, and the business integration from farm to retail outlet, all require scrutiny since they determine the characteristics of intensive livestock production.

All the arguments for intensive farming are economic, and the economic argument about animal welfare is that animals looked after improperly will not grow, or produce, maximally. Economic incentives automatically ensure the well-being of the hen in her cage, or the calf in its crate. The Brambell Committee rejects this incomplete analysis, and concludes that some common practices, such as the de-beaking of poultry, the docking of pigs and the yoking or close tethering of calves, are both cruel and inefficient. The opponents of 'intensivism' therefore find their views supported in these particulars.

The critics of intensive animal husbandry have stated their case in terms of more general humanitarian arguments, too, and it is the great merit of the Brambell Committee that it has not ignored this and limited its interest only to the physical well-being of the animal. The Committee has also tried to assess the effects of present husbandry practices on the mental well-being of animals, and, in so doing, has set a most interesting and important precedent. In taking this step it considered not only the evidence from anatomy and physiology relevant to stress-causing circumstances, but also more recent researches into animal behaviour. Furthermore, it specifically states that it is "concerned with the welfare of the animal throughout what may be the duration of its life", so that what may be tolerable short-term conditions of stress, discomfort or deprivation are reviewed in their life-time context, and given as much weight, where necessary, as more acute, but transitory, suffering. Obviously our information about the mental well-being of domesticated animals is very sketchy, since many of the necessary behavioural studies have still to be made, and the Committee's conclusions with respect to such systems as battery cages for hens may seem tentative on this account. However, it also recommends, as a necessary part of a new Act to replace existing, inadequate, animal-welfare legislation, that a Statutory Farm Animals Welfare Standing Advisory Committee should be set up to advise Ministers. That is, the Brambell Committee envisages the line, which it has itself drawn, so as to include mental, as well as physical, suffering of animals, becoming more clearly defined by future behavioural researches, and it expects subsequent legislation to take account of this.

The Committee's arguments in assessing pain, stress and behavioural aspects of suffering are elegantly set out in an appendix to the report, prepared by Prof. W. H. Thorpe. This reviews recent anatomical-physiological and ethological knowledge, first in general terms and then specifically for the fowl and for the domesticated ungulates. The need for basic behavioural research is clearly indicated by this review, which emphasizes the fragmentary nature of our present knowledge about the animals most closely associated with man. Perhaps the equally pressing need for investigations on the handling of these animals without stress by developing training régimes, skilful handling procedures and new husbandry methods, is not sufficiently emphasized. But few will disagree with Prof. Thorpe's conclusion: "Whilst accepting the need for much restriction, we must draw the line at conditions which completely suppress all or nearly all the natural, instinctive urges and behaviour patterns characteristic of actions appropriate to the high degree of social organization as found in the ancestral wild species and which have been little, if at all, bred out in the process of domestication. In particular, it is clearly cruel so to restrain an animal for a large part of its life that it cannot use any of its normal locomotory behaviour patterns". Pet lovers, who have been especially vocal against 'factory farming', should pay particular attention to this humane conclusion.

Of course the Committee does not find that all intensive methods are improper, and it emphasizes that, compared with traditional practices, they frequently provide a healthier environment in which suffering from disease can be quickly and effectively controlled and where cold and damp can be minimized. Developments in intensive husbandry have brought positive achievements, which are reflected in improved yields and efficiency of food conversion. The case for retaining the battery cage is an interesting example of this, for two reasons. First, traditional 'free range' flocks are liable to chronic infection by internal parasites, are muddy and dirty, and uneconomic in the use of manpower, and to revert to them now would be a retrograde step. Secondly, the alternative intensive methods, the battery system or loose housing on deep litter, each have disadvantages: the former involves restriction of the physical movement of the birds, including such ingrained behaviour patterns as flying, ground scratching and dust bathing; the latter exposes the birds to infection (for example, coccidiosis) and to persecution by their fellows due to the inability of lower members in the peck order to escape from their social superiors. The Committee, therefore, reluctantly concludes that a modified battery system may be as good as, or even better than, loose housing from the point of view of the birds. But it then lays down more rigorous requirements of space for each bird, of birds for each cage, of

* *Report of the Technical Committee to Enquire into the Welfare of Animals kept under Intensive Livestock Husbandry Systems.* Pp. v+85. (Cmnd. 2836.) (London: H.M.S.O., 1965.) 6*s.* 6*d.* net.

details of construction and siting of cages, and of ventilation and illumination of poultry houses, than have been usual in the industry. It is recognized that these changes may result in increased production costs and in higher prices to the consumer.

A great deal of attention is directed to the space needed by intensively kept animals, as well as to the types of flooring provided for them to stand or lie on and the temperatures and humidities they must tolerate. It is obvious that an ecology of farm animals is required to refine the approximate standards now laid down. Such ecological studies, like further work on the behaviour of farm animals, would be expected to improve the efficiency, as well as the humanity, of intensive production techniques. It is important that they should be initiated immediately, as intensive farming must grow to meet ever-rising food requirements.

One further point deserves comment. The Brambell Committee is greatly impressed (and rightly so) by the importance of the standard of management and stockmanship for the welfare of livestock. The amount of equipment and the numbers of animals in the care of one individual (10,000 or more laying birds in a modern, environment controlled house, for example) sets requirements of knowledge, skill and dexterity of a different order from those traditional in agriculture. At present, agricultural education does not match this requirement, and agricultural wage structure does not provide the rewards concomitant with acquisition of suitable qualifications. The Committee is right, therefore, to emphasize both needs. A more humane intensive farming may attract the necessary calibre of stockman: if the Brambell Committee's recommendations are put into effect he will also stand less chance of being degraded by some of the practices of his trade.

There have been fewer comments on this Committee's report than might have been expected, and this is probably a measure of its skill at striking a balance between the practical and the desirable. It is interesting that they have met the six points of Mrs. Harrison's charter for animal welfare†, either by calling for a modification of the present techniques (as with battery cages, the methods of 'white' veal production or the use of slatted floors), or by agreeing that they should be prohibited (as with the use of deficiency diets, permanent tethering and dim lighting). It is disturbing that research has often been used to support these practices, which are now found to be wrong. If the care which the Brambell Committee has given to its report is also given to framing the terms of reference of the much-needed future research, this error may be avoided. More research will also show whether the Committee is correct in its fundamental assumptions about the feelings and emotions of animals. Meanwhile, no humane society can do other than accept its thesis.

† Harrison, Ruth, *Animal Machines* (Vincent Stuart, London, 1964).

DIAMOND

Physical Properties of Diamond

Edited by R. Berman. Pp. xii+443. (Oxford: Clarendon Press; London: Oxford University Press, 1965.) 75*s*. net.

PHYSICAL Properties of Diamond places diamond firmly in the centre of modern solid-state physics.

More than one civilization has had its interest and imagination stirred by diamond in diverse ways. In the framework of the physical metrical approach, which characterizes our own, it is striking to find that a substance which at first sight seems uniquely simple, from a crystallographic point of view, in fact exhibits a rich complexity of properties. This receives comment by E. W. J. Mitchell concerning radiation damage in diamond: "What has been surprising, and scientifically stimulating, has been the number of effects which have a fundamental significance in solid-state physics generally. These effects are most readily seen in diamond, being a covalent structure of high Debye temperature (θ_D). In this connexion matters of particular interest include:

(*a*) The structure in absorption and emission spectra and its interpretation in terms of zero and multi-phonon interactions.

(*b*) The sharp infra-red lines associated with the acceptor lines in semiconducting diamond.

(*c*) The occurrence in the presence of defects of the normally forbidden 1-phonon vibrational absorption."

Corresponding statements might be made about many of the other fourteen chapters in this book, which constitute a unique collection of monographs by scientists working personally in the very diverse fields they discuss. The fact that they all refer to the same remarkable solid pulls the book together in a striking and suggestive way. Quite often substantial portions of the researches described in the text have not hitherto been published elsewhere. Sometimes they must even be described as obviously unfinished. As a result, a fresh and intensive discussion of many important problems in the general physics of the solid state is presented in this book, focused in terms of the properties of diamond. Furthermore, investigations of the hardness, of surface grinding and surface imperfections, and of the anisotropy of various physical properties, would, at present, be difficult to match for many other crystals. In these respects, the book should serve as a valuable study text for advanced honours and postgraduate courses on the solid state.

Various physical properties are discussed under the headings: X-ray diffraction studies on diamond and some related materials, X-ray topography, transmission electron microscopy, optical studies, ring cracks on diamond surfaces, deformation, friction and wear, hardness and wear during grinding and polishing, electronic structure, paramagnetic resonance, optical properties of natural diamonds, semiconducting diamond, the counting properties of diamonds under ionizing radiations, thermal properties, and radiation damage. These will naturally attract varied attention; possibly also some controversy, partly because their relation to cognate problems in other crystals is incompletely developed.

Such relationships are not always brought out sufficiently in the text, perhaps because of its poly-monograph structure. In fact, an additional chapter dealing with correlations in the widest sense between diamond and diamond-like assemblies of other atoms could have been very informative. Various authors discuss from different points of view substitutional inclusions of nitrogen atoms, the concentration of which may rise above 0·2 atoms per cent in certain types of diamond. But little or no mention is made of the topographical segregation of any other impurity atoms in diamond. This general problem would have been further illuminated by brief reference to segregation phenomena of hetero-atoms in other types of crystals, in which partly ordered defects may occur and may present suggestive analogies.

Modern studies of the physics of the solid state merge inextricably with much chemical physics. Tantalizing comments are to be found, here and there in the text, on various oxidative techniques of etching of diamond surfaces. Though these are used to reveal various defects of structure, there is little or no discussion of more chemical aspects of the attack, the details of which may actually help to throw light on the physical problems

envisaged. Thus much closer scrutiny seems warranted of the structure and location of the "free surface carbon" formed in the course of applying certain oxidation techniques to diamond (p. 120). Formation mechanisms of such 'carbon' may conceivably be related to basic features of the kinetics of migration of carbon atoms in diamond crystals, as well as in dislocation bundles, or in the gas/solid interface. Etching of diamond, by media which act as solvents for carbon, and not merely as oxidizing agents, could also yield complementary information about a number of structural problems.

As a development of this theme, it would clearly be useful to have more general information about the kinetics of graphitization of diamond, including experiments under conditions where the role of oxygen at the interfaces can be definitely excluded. Similarly, in this book discussion of thermal annealing of defects, whether natural or produced by irradiation, scarcely pays sufficiently detailed attention to kinetic aspects.

Since the inception, in 1949, of co-operative researches published in this book, technological mastery has been achieved of production of synthetic diamond. In view of this success, chapters on the chemical physics of its nucleation and growth from solvents or from graphite now seem definitely called for. But, despite various insufficiencies of chemical physics, the book has many admirable features. It is a worthy tribute to the originators of this programme of research on diamond, Sir Ernest Oppenheimer and Sir Francis Simon. The editor, Dr. R. Berman, also contributes a lucid chapter on the thermodynamic properties of diamond and on its thermal conductivity. This completes a fine task, in bringing a mettlesome team of contributors to such an effective goal.

A. R. Ubbelohde

UNDERSTANDING SOLIDS

Principles of the Theory of Solids

By Prof. J. M. Ziman. Pp. xiii + 360. (Cambridge: At the University Press, 1964.) 45*s*. net; 8.50 dollars.

Principles of the Theory of Solids is an admirable book. Though it will certainly reach a much wider audience, it is designed specifically as a text-book for graduate students in solid-state physics, and it is ideally suited for that purpose. As Prof. Ziman reminds us in his preface, the aim of a text-book should be to explain ideas, rather than to catalogue facts; by restricting himself to a few of the basic themes of solid-state physics—broadly speaking, electrons, phonons, and their interactions—he has been able to explore the ideas in considerable depth, explain them with admirable clarity, and bring out in full the underlying unity of the topic.

The reader is assumed to be familiar with the basic techniques of quantum mechanics, including time-dependent perturbation theory and scattering theory, and to have some idea of what creation and annihilation operators are; he is also assumed to know something of the basic experimental facts of solid-state physics. The book is exclusively concerned with theoretical concepts, rather than experimental facts: one will look in vain here for tables of Debye temperatures or electronic specific heats, and the copious figures—one hundred and seventy-four of them—are all designed to illustrate the theoretical argument; not one of them shows an experimental point. But the theoretical argument is beautifully developed, and the chapter on electron states, in particular, is a model of exposition. The approach is thoroughly contemporary throughout, so that, for example, electron–electron interactions are discussed entirely in terms of the dielectric function. No attempt is made to deal with Green's function techniques, bubble diagrams, and the other sophisticated abstractions of modern theoretical physics, but outside this highly specialized area most of the ideas now used in electron–phonon physics are discussed, analysed, and explained, so that after studying the book a student should be in a position to comprehend much of the present-day literature in this field.

Graduate text-books nowadays commonly include a set of problems at the end of each chapter, for the student to try his strength on. In the present text, there seem at first glance to be no problems, but the reader will rapidly find that the book, in fact, abounds in them: they are embedded in the text on almost every page. The author's technique is to sketch in lightly the steps in each theoretical argument, so that the line of thought is not too much obscured by algebraic detail, but to leave the reader enough clues to fill in the details for himself if he will. If he does, he will learn a great deal more about the subject.

He will also, it must be added, discover a good many obscurities and a good many minor errors in the text. Because the exposition is otherwise so excellent, these lapses may puzzle the unassisted student more than they would in a lesser book, and it may be worth giving a few examples. They are particularly frequent in the chapter on optical properties, where it is not always clear whether the author is talking about metals, or insulators, or both. If the reader has been taught to distinguish the ideas behind the Lorentz and Onsager treatments of the internal field problem, he may be a little puzzled by Fig. 114; he may or may not be puzzled by equation (8.12) and by the (spurious) argument leading to equation (8.80), but he should be. He will certainly be puzzled by equation (8.110), which—the author claims—reproduces (8.7). To see that this is so, the reader has first to detect and correct an error in sign in (8.110), and then to realize that N^2 in (8.7) becomes ε in (8.110), and ε in (8.7) becomes 1 in (8.110). All this is rather a lot to ask of the struggling graduate student. He is less likely to be puzzled by Fig. 91(*b*), which is clearly wrong.

The structural unity of the book is weakened, perhaps inevitably, by the penultimate chapter on magnetism. This discusses a whole miscellany of topics, ranging from the elementary Weiss theory of ferromagnetism through the Ising problem to a summary of the theory of ferromagnetic and antiferromagnetic spin waves. The latter topic is closest in spirit to the rest of the book, and it also serves to illustrate the use of creation and annihilation operators, in preparation for the excellent final chapter on superconductivity. But unhappily the treatment of spin waves is rather too brief to be useful, and just at this point the physical ideas, where they are most needed, tend to become submerged in the algebra: the graduate student will find this section rather heavy going.

Despite these minor criticisms, it remains true that this is an admirable book. Indeed, it scarcely needs my commendation: it is already being widely used as a graduate text on both sides of the Atlantic. It seems likely that a second edition will soon be called for, and we may hope that it will be even better than the first.

R. G. Chambers

A BIOLOGIST'S GUIDE TO TRANSISTORS AND OTHER SEMICONDUCTORS

Instrumentation with Semiconductors for Medical Researchers

By Prof. Clinton C. Brown, in consultation with George N. Webb. (A Monograph in The Bannerstone Division of American Lectures in Objective Psychiatry.) Pp. xvii + 254. (Springfield, Ill.: Charles C. Thomas, 1964.) 10.50 dollars.

A LARGE proportion of handbooks which aim to provide information over a complete field are either written by a panel of authors with carefully defined terms of reference, or, if by a single author, represent a course of

lectures which over the years has been modified and polished until the author feels it represents the perfect approach to his subject. These methods help to ensure completeness and accuracy, but too often fail to produce a readable book. In this book Clinton Brown and George Webb have followed a different course. Dr. Brown is clearly a man with wide and extensive knowledge of his subject—both biologically and electronically—as well as a rare gift for putting across his ideas. It would almost be worth having this book for the first chapter alone, for there can be few biologists who would not find something of value in this discourse on the use—and misuse—of instrumentation in biology to-day and in the foreseeable future. The whole chapter is eminently quotable, but one short passage must suffice: "Reduced power, space and weight are obvious advantages of the transistorized instrument but their greatest importance has been in the invention of new devices. The descendants of the transistor; the four layer diode, semiconductor strain element, photosensitive device, controlled rectifier, Esaki diode are such radical departures from the original transistor as to resemble new species. Commercial applications are available to-day for functions formerly considered impossible or impractical". The quotation is significant: one suspects that Mr. Webb (the electronic collaborator) made it a point of honour to see that no new device of bioelectronic value was omitted, and as the book proceeds the distinctions between, for example, different types of four layer diodes is clearly explained with ample indication of typical circuit configurations.

One inevitable flaw in a book which has virtually been written by one man—and almost certainly over a short period—is that a number of inaccuracies and inconsistencies have slipped in. Misprints such as (p. 43) $X_L = 2$ *pi fL* are not misleading, but on this side of the Atlantic some readers may be caught out by the statement that the current in a hundred-watt lamp is about one amp (p. 35). (No voltage is stated.) More misleading is the implication that capacitors in series are additive (Colpitts oscillator, p. 157), while the statement that transformer coupling is unsatisfactory "at the low power and low frequencies encountered" (p. 121) surely requires further comment since no indication is given that two quite separate problems are involved. Again in one or two places the legends on the diagrams do not agree with the text, but in one place (p. 75) both diagram and text are wrong: "In (Fig. 5: 14*B*) the signal increases smoothly from zero to some value where it drops to zero. The differential of this signal is a square wave".

It is difficult to comment on some numerical data without knowing which devices the author has in mind, but he describes a CdS cell illuminated at 400 c/s by a neon lamp (p. 140) as a form of chopper for a d.c. amplifier. I feel that this could be misleading as, while high-speed CdSe cells are available, the vast majority of photosensitive resistors would not follow this frequency satisfactorily. On the other hand, to say (p. 102) that the reverse current in a diode is "less than 5 per cent" seems very cautious, even by germanium standards. A typical silicon leakage figure would be 0·1 μamp for a diode with a maximum forward current of 100 m.amp (Mullard *OA* 200) while a forward/reverse ratio of a thousand is now common even among germanium devices.

Although, rather surprisingly, abbreviations Ω, KΩ, MΩ, A, mA, μA, nA, etc., are not explained, their omission is the more conspicuous since the development of symbolism and ideas is elsewhere excellent: the chapter on signal conditioning systems and on digital logic being particularly good.

To sum up: this book is well written, amply and skilfully illustrated and, despite numerous minor lapses, should be of great value both to bioengineers and to biologists. It does not describe any complete apparatus—that is not its object—but it does describe clearly and in simple terms the working of virtually every semiconductor device available to-day and discusses ways in which apparatus built around such devices can be profitably used in a biological laboratory.

J. R. B. Greer

SOVIET CHEMISTRY

Chemistry in the Soviet Union

By Prof. John Turkevich. Pp. ix + 566. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1965.) 93*s*.

At a meeting of the Russian Chemical Society on March 6, 1869, the periodic law was first presented to the world by Menshutkin, acting for Mendeleev, who was ill. Mendeleev later became the 'best-known Russian chemist'. In conformity with Prof. Turkevich's treatment of other topics, he should have mentioned Newlands of London, who in all essential detail presented the same concept in 1864; and these few years were critical in the matter of atomic weights. Ignored is the letter in *Chemical News* of 1882 (p. 278) in which Newlands remarks on the reception of the Davy Medal by Mendeleev "for his discovery of the periodic relation", and draws attention to his own publications of 1864 and 1865. Ignored, too, is the letter by Mendeleev himself in *Chemical News* of 1881 (p. 15), in which he admits "it is possible that Newlands has prior to me enunciated something similar to the periodic law".

Those of us brought up in the classical days will recall the full-sounding names of Lomonosov (1711–1765), Tschitschibaban and Zelinski. Klaus contributed to the knowledge of the chemistry of osmium and iridium, and in 1844 discovered ruthenium, named after the Latin name for Russia. P. Walden worked mainly on non-aqueous electrolytic solutions; but is best known for his isolated discovery of the optical inversion.

This book is mainly about Russian chemists and educational (research) institutes. The history of chemistry in Russia from the fifteenth to the middle of the nineteenth centuries is outlined in six pages, and, in 12 pages, prominent chemists in the second half of the nineteenth century are mentioned. We read that Butlerov (1826–1886) is given credit by Western authorities for introducing the expression 'structure' into organic chemistry; but the Soviet chemists now claim a greater role for him as the one who formulated the structural theory of organic chemistry. "The solution of this problem could only be the lot of a scientist that is not only of outstanding talent but also free from the enumerated (p. 36) shortcomings which were inherent in the majority of important Western European chemists." "The honour of creating a new theory which exerted a revolutionary influence on further development of organic chemistry, fell to a Russian chemist, A. M. Butlerov." "The standard text-books in the West do not mention his eminence in this role." Markovnikov (1838–1904), a student of Butlerov, was a leader of the Russian scientific circles of his period.

In the next 29 pages, chemistry in Russia in the nineteenth and twentieth centuries is summarized under the usual headings, such as organic, colloid, analytical chemistry; and similar summaries on Soviet chemistry between the two World Wars are given in 91 pages.

For those who have maturity and time for quiet thoughtful reading at home, these 140 pages can provide intensive pleasure, and a grasp of the activities of Russian chemists not otherwise so readily achieved. There are 30 helpful pages on the activities of chemical research establishments in the U.S.S.R., but the remaining 393 pages could well have been relegated to a library handbook; for these show a list of names of authors, and the titles of dissertations in chemistry at the Soviet universities, as well as a similar list of recent publications of members of the U.S.S.R. Academy of Sciences.

W. Gerrard

EPOXIDES AND THEIR DERIVATIVES

Epoxides and Their Derivatives

By M. S. Malinovskii. Translated from the Russian. Pp. xvii+493. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 144*s*.

THERE are now extant a number of reviews and monographs covering the chemistry of epoxides and their derivatives, and *Epoxides and Their Derivatives* is a commendable effort to provide chemists with a source-book wherein they might find the preparation and reactions of epoxides summarized, together with relevant references to the literature. The obvious limitation is that the literature here covered is only that up to 1958: the book was published in Moscow in 1961, and is now made available in English through the Israel Program for Scientific Translations.

The monograph is conveniently divided into three parts. The first part deals with the structure and reactivity of epoxides, their classification and nomenclature. The second covers the preparation of epoxides, and the third is an extensive review of their reactions to include their hydration, hydrogenation, isomerization, and polymerization, and reactions with alcohols, aldehydes, ketones, amines, organo-metallic compounds, mercaptans and nitrogen heterocycles. Part of the usefulness of the last two sections is that often details of the experimental procedures used are reprinted.

The book concludes with tables of known epoxides in order of their molecular formulae, giving their physical properties. The index is very good, and is not the least useful part of the monograph.

It has to be recognized that the origin of this work is a Russian one, and at times a nationalistic concern is apparent. The introduction includes a reference to Khrushchev's address to the twenty-second Congress of the Communist Party of the U.S.S.R. setting out the aims of Soviet chemical industry, and very frequently the authors attributed as having first made reference to a compound are Russian ones. There are sweeping statements such as "the preparation of ethylene oxide from ethylene chlorohydrin has been thoroughly explained in Soviet literature" (p. 69), and it appears that "Zimakov and Petrov (in 1946) were the first to explain the reactivity of ethylene oxide according to modern concepts" (p. 13): this in spite of the work of Bronsted and the Kilpatricks in 1929. Against this background it looks like wilful misinterpretation on page 113 when the conclusions of Bronsted about his own work are discussed. One of the weaknesses of the book is the lack of a thorough review of the mechanisms of the ring-opening of epoxides.

It is thus politically unfortunate that, in translation, American spellings have been adopted. It must be inevitable that certain phrases in translation appear strange to the reader, particularly when the phrase originally had to be translated into Russian. An example is the determination of bond-lengths by electron-diffraction referred to as investigation of electronograms (p. 3). But these, and other small textual points, should not be allowed to detract from the fact that this is a very useful survey which should find its place among the reference works of most research libraries.

J. Biggs

ASPECTS OF ENZYMES

An Introduction to the Study of Enzymes

By Dr. H. Gutfreund. Pp. x+335. (Oxford: Blackwell Scientific Publications, 1965.) 60*s*. net.

An Introduction to the Study of Enzymes is intended "to give an account of theoretical and experimental methods for the study of enzymes" and "to introduce the reader to the basic principles of the concepts of enzyme kinetics, to methods for kinetic investigations and to their interpretation". The author admits a bias towards the purely kinetic analysis of the behaviour of enzymes. In a sense, biochemistry is the study of enzymes, and perhaps a more accurate title for the book would be *An Introduction to the Study of Enzyme Mechanisms*. Obviously all aspects of enzymology cannot be embraced even superficially in a single short book, and the isolation of enzymes, for example, is not considered.

Dr. Gutfreund succeeds very well in his aim of giving a readable, introductory account to whet the reader's appetite, especially in those sections of the book which deal with experimental methods and the interpretation of results. He repeatedly points to limitations in the treatment and advises the reader to turn to more detailed sources. The selection of some 500 references includes some papers published in 1964, and an adequate general index is supplemented by a useful index of the enzymes discussed.

Minor blemishes include the occasional use of DPN as well as NAD, and the absence of page references when figures and tables in other parts of the book are under discussion. In the introductory chapter, which includes a helpful outline of applications of digital and analogue computors in enzyme kinetics, a steady-state definition of the Michaelis constant in the original Michaelis–Menten formulation is confusing. A suggestion that prosthetic groups as well as coenzymes should be treated as substrates is corrected later in the book, but then prosthetic groups are said to be present in 1 : 1 molar ratio to the enzyme.

The following two chapters on formal enzyme kinetics make up one-third of the book. The somewhat diffuse style of the author is perhaps less suited to these theoretical treatments than to the later, more descriptive parts of the book, although asides such as "statistical methods can never be a substitute for adequate experimental data" are illuminating. Unfortunately for the student, these chapters contain more than an acceptable number of errors and misprints in the kinetic expressions, and vagaries of punctuation and syntax largely absent from the rest of the book. Generally, adequate coverage of the usual topics and algebra are provided, together with useful sections on solvent effects, diffusion-controlled reactions and activation by metals. I found the treatment of inhibition confusing, and there seemed to be misconceptions about non-competitive inhibition. Steady-state and equilibrium treatments of a non-competitive mechanism are not equivalent, as they are said to be here, and the possibility of inferring quasi-equilibrium conditions is based on this fact.

Chapter 4 is an admirable account of special techniques for following enzyme reactions, and includes rapid reaction techniques, spectrophotometry and fluorometry, hydrogen ion, oxygen and carbon dioxide concentration measurements, and calorimetry. This lucid survey, and the following chapter on the protein chemistry of enzymes and the active site, can be recommended to both undergraduates and advanced students.

Chapter 6 brings together various applications of isotopes in a satisfactory manner, and includes, with many examples from the literature, the interpretation of isotope rate effects, stereospecificity studies and exchange reactions. In relation to this and the following two chapters, in which various types of evidence of mechanism are reviewed for a good selection of group-transfer reactions, it seems a pity that a closer correlation was not made between isotope exchange, kinetic and other means of distinguishing between the single and double displacement mechanisms, although this would require a more detailed account of the kinetics of two-substrate reactions than is given in Chapter 1. The book closes with some general remarks on the nature of enzyme action, and brief indications of some mechanisms of metabolic control.

With some reservations about the earlier chapters, this book can be recommended to students and research

workers as a personal, enjoyable and stimulating survey of the study of enzyme mechanisms, which demands little prior knowledge of the subject and is reasonable in price.

K. Dalziel

INTRACELLULAR MEMBRANES

Intracellular Membraneous Structure

(Proceedings of the 1st International Symposium for Cellular Chemistry.) Edited by S. Seno and E. V. Cowdry. Pp. xix+588. (Okayama, Japan: Japan Society for Cell Biology, 1965.) 14 dollars.

SCIENTIFIC conferences and symposia are nowadays frequently followed by publication of an edited version of the proceedings in elaborate book-form. The question arises whether these volumes are a worth-while investment bearing in mind the cost, inevitable time lag in publication, and the probability that the contributors will in any case report their observations elsewhere. In spite of these material drawbacks, the bound volume can certainly, sometimes, be justified, either through well-judged timing of the symposium or perhaps the authoritative nature of particular contributions. On both of these counts there is much to recommend the special Katsunuma Memorial issue from the Japan Society for Cell Biology, entitled *Intracellular Membraneous Structure*.

The meeting was held at Ohtsu, during March 1963, and it is clear that from a technical point of view much of the work presented reached a very high standard. The invited speakers were concerned primarily with ultrastructural aspects of cell physiology and pathology; and the papers are divided into six sections covering various categories of cell membranes. Original references, and a transcript of the discussion that followed the verbal presentations, are included. Altogether there are 43 papers (all in English) mostly emanating from laboratories in Japan and the United States. Numerous first-rate and well-reproduced electron micrographs are included as illustrations.

In the opening section, "Endoplasmic Reticulum", D. W. Fawcett describes the varying patterns of granular and agranular reticulum in cells of the mammalian pancreas, liver and testis, in different functional states. There is discussion of the possible role of the endoplasmic reticulum and the Golgi apparatus in the formation of secretory products. Several later papers touch on this question, and serve to illustrate clearly one of the difficulties most commonly met with in biological electron microscopy; namely, the interpretation of profiles that seem to suggest a dynamic inter-relation of cell components. Interesting papers by E. Yamada on membrane-limited elements in retinal cells of the cat, and by Y. Miura and H. Itoh on fibroin-synthesizing vesicles in silk-glands, are included in this section. Next, under "Mitochondria and Related Structure", two papers from D. E. Green and associates and another from F. S. Sjöstrand give an instructive view of present-day thought (much of it rather speculative) on ultrastructure, chemistry and function in mitochondrial membranes. Papers on the morphology of chloroplasts also appear in this chapter.

All microscopists who have ever been fascinated and perplexed by the Golgi controversy, dating from 1898 when Dr. Golgi reported the "apparato reticulare interno" in certain neurones, will acknowledge gratefully the contribution of electron microscopy towards recent clarification of this problem. Out of nine papers on the subject in this symposium two of special interest are by G. C. Hirsch, who strives convincingly to correlate the earlier images, based on methods of light microscopy, with the complex patterns of membranous lamellae and vesicles now familiar to electron microscopists. Further consideration of the role of the Golgi apparatus in secretory cells is presented by L. Herman and associates in a technically most impressive contribution, and the recent extension of cytochemical methods to the ultrastructural level is elegantly demonstrated by A. B. Novikoff in a comprehensive account of enzymatic activities and possible functional inter-relation of the various intracellular membrane systems. Notable in later sections of the book are an assessment by C. A. Baud of possible morphological pathways for nucleo-cytoplasmic exchange of materials; and reviews by J. D. Robertson on the present status of the unit membrane concept, and by E. V. Cowdry on the intracellular distribution of water. Finally, there are papers on the outer cell membrane itself, and mechanisms of transportation across it; these include reports on synaptic morphology, on the absorption of fat by cells of the intestinal epithelium, and on various examples of endocytotic activity.

In spite of its rather high price, this book can be recommended as a well-produced, up-to-date and potentially useful acquisition for the bookshelves of cell biologists.

J. A. Armstrong

A LAYMAN'S LOOK AT BACTERIA

Focus on Bacteria

By Emmy Klieneberger-Nobel. With a chapter on the Mycoplasmataceae by Ruth M. Lemcke. Pp. vii+145. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965.) 32*s*. 6*d*.

IN several ways, *Focus on Bacteria* is an odd little book. The jacket flap says it "is not intended for the specialist but for the lay person with keen scientific interest". The author's foreword states: "The purpose of this book is first and foremost to show that nature has a quality of beauty even in her smallest manifestations".

The first chapter is a brief historical sketch of the development of bacteriology as a science, covering the fundamental discoveries of the father of microbiology, Antony van Leeuwenhoek, in the seventeenth century and highlighting the great names of the nineteenth century.

Chapter 2 outlines in three pages the methods of microscopical demonstration available to the microbiologist; rather too briefly in view of the fact that the book is copiously illustrated with photomicrographs and electron micrographs and the lay reader would probably like to know a little more about how they were obtained. This is followed by a short chapter (five pages) on "Diagnostic Bacteriology".

The bulk of the text is presented in Chapter 4 under the title "Bacterial Anatomy" and the various anatomical features—flagella, capsules, cell wall, internal composition and endospores—are dealt with under sub-headings.

Chapter 5 takes a brief look at bacteriophages and Chapter 6 at bacterial genetics. Chapter 7 has three sub-headings, "The Myxobacteria", "The Streptomycetes" and "Therapeutic Substances". Chapter 8 deals with the "Mycoplasmataceae". There follows a 14-page glossary, a page of references and a subject index.

There are about 60 photographic plates and about 20 line drawings. In general, the plates are of a very high standard, some of them spectacular (even though they have been printed elsewhere). It is a good thing, too, that the references to the papers from which the plates have been taken have been retained.

One of the problems about this book seems to have been an uncertainty about the level at which it should be maintained. It is written in a straightforward, sometimes over-simple way, yet the list of references includes some advanced texts that could scarcely be recommended reading for the layman. Over-simplification has also led to some odd statements, for example: "Two points closer together than half the wavelength of white light cannot be seen as

two different points; half the wavelength of white light is 0·00025 mm . . ."; and "the order of the Actinomycetaceae comprises two families, namely Actinomycetes and Streptomycetes". The experiment quoted to demonstrate that "a streptomycin-sensitive population produces as a rule a few resistant organisms, though it has never been in contact with streptomycin before" is not proof of this. Odd, too, that the chapter on the pleuropneumonia-like organisms has been contributed by Dr. Ruth Lemcke when the jacket quotes, in regard to Dr. Klieneberger-Nobel's book on these organisms, a reviewer who states: "Dr. Klieneberger-Nobel is our greatest authority on this group". The table of contents is incomplete, and surely it was unnecessary to include 'descriptions' of oxygen, hydrogen and nitrogen in the glossary.

L. B. QUESNEL

BACKGROUND TO MALARIA

Migrants and Malaria

By R. Mansell Prothero. Pp. x+142. (London: Longmans, Green and Co., Ltd., 1965.) 15*s*. net.

HERE is something new by a geographer for the epidemiologist, which the latter can study with both interest and profit, whether his concern be in malaria or in any other communicable diseases. It is not new that there should be some overlap in the fields of interest of the two, but the overlap has in the past been usually approached from the medical side, with an effort to explain known epidemiological happenings and timings on the basis of geographical factors. In *Migrants and Malaria* the approach is reversed: the geographer explains one aspect of his own subject, developing it in its own right and then examining the effect which it might have on subsequent epidemiology.

On the basis of an original interest first expanded by contact with malaria prevention in Northern Nigeria, Dr. Prothero sets out a general statement of the nature of migration in Africa, and elaborates it by special studies of the forms which it takes in the Republic of Sudan, the Horn of Africa, east and south Central Africa, West Africa and Morocco. He prefaces this with an explanation of the nature of malaria and the means by which it is prevented, and in each case studied he refers to some malaria eradication project and the ways in which migration has affected its progress.

The section on migrants classifies and describes the different types of movement, pastoral, nomadic, transhumance (movement at particular times of the year from one grazing area to another by relatively well-defined routes), pilgrimage and local population movements. Each of these aspects is not only lucidly described, but is also well illustrated by maps sufficient to give a very clear impression to the geographical novice. Some types of migration are further analysed in the local studies with special reference to their effects on malaria eradication, and even the experienced malariologist may be brought up suddenly by the realization that 85 per cent of the population of the Horn of Africa is nomadic. He may be made thereby to think hard about possible consequences: reintroduction of malaria into places from which it may have been cleared; the difficulty of spraying insecticides in houses or shelters which are in fact evanescent; and the virtual impossibility of carrying out a case-finding and treatment mechanism among populations which move overnight. The Horn of Africa is an extreme case, but the author brings out the fact that, by the standards of Europe, migration in all African countries constitutes an extreme case and must be taken into account in the special context of malaria eradication and in all epidemiological studies.

The book is well written and, though a paper-back, is well produced. It is said to be a forerunner of a series to be written by geographers and dealing essentially with their activities. If the other members of the series can keep up the standard set by Dr. Prothero, it will be a significant contribution to the understanding of geographers and of their work by followers of other disciplines.

G. MACDONALD

LABORATORY DESIGN

Chemistry and Biology Laboratories

Design-Construction-Equipment. By W. Schramm. Translated by Mrs. M. Jansen. Pp. x+255. (London: Oxford and New York: Pergamon Press, 1965.) 105*s*.

UNDOUBTEDLY there is a shortage of books on laboratory design, construction and equipment; any addition to their number, providing ideas and information which may assist in improving laboratories in these respects, is therefore welcome. *Chemistry and Biology Laboratories* is an international survey, although quite naturally Dr. W. Schramm has a predominant interest in German laboratories.

In general the translation of the text seems satisfactory; the odd strange expression does, however, creep in (such as service 'spline' by which is probably meant service duct). The use of German proprietary names for materials has also not been entirely avoided. A misleading statement is "to avoid the stroboscopic effects of fluorescent lighting the benches should be equipped with alternating current outlets".

Many interesting and highly specialized designs for benches and fume cupboards are described, including the use of movable benches with service ducts available on the walls or as floor standing columns. There is also a brief treatment of the problems and solutions of air balance difficulties in laboratories with fume cupboards. Other matters discussed include the layouts suitable for various types of laboratory and the arrangements for services. Many examples are given both of individual laboratories and specially designed buildings.

The book may well be criticized on various grounds. First, for a book selling at five guineas the quality of the reproduction of the photographs leaves much to be desired, so much so that some points they are supposed to illustrate are lost. It does not appear that any critical attention has been given in the selection of the illustrations, so that the reader is not given much help in selecting what is best, even if he is interested in designing a general purpose laboratory. While Britain is eventually to use the metric system, architects, builders and chemists still use feet and inches for measuring working space, so it is a pity that these measurements could not have been translated into familiar units.

The grading of laboratories on p. 142 is based on the curie level of radioactivity and not on the specific hazards of particular isotopes. Thus, according to the Medical Research Council memorandum, up to 10 curies of tritium or mercury-197 could be handled in a grade '*C*' laboratory (any good conventional laboratory with an efficient fume cupboard), while from this book one would expect to have to use a 'hot' laboratory. In general the stress here is not 'hot' laboratories, whereas a great deal of radiochemical work needs less-elaborate accommodation.

The photographs of shielded cupboards, etc., give no idea of dimensions, thickness of shielding, etc. This was probably included in the statistical information omitted from the English edition. Glove boxes are mentioned for β-emitters, but no mention is made of α-emitters, for example, plutonium. One might not need glove boxes for working with β-emitters in solution.

After all these criticisms have been made, the reader will nevertheless find a lot of useful information and the bibliography is considerable though mostly of German origin.

A. A. W. RUSSELL

Encyclopedia of Polymer Science and Technology

Plastics, Resins, Rubbers, Fibres. Edited by Herman F. Mark, Norman G. Gaylord, Norbet M. Bikales. Vol. 2: Amino Resins to Casein. Pp. xiii+871. (New York and London: Interscience Publications, a Division of John Wiley and Sons, Inc., 1965.) 375*s*.

THE object of this ten-volume encyclopedia is no less than the coverage of both the science and technology of polymers. Volume 1 started with "Ablative Polymers" and in some 893 pages reached "Amino Acids". Volume 2 takes us to "Casein" in a similar large number of large pages. Fifty topics are dealt with according to the space the various contributors and the editors consider they merit, from one sentence for "A-Stage" (resins) to 95 pages for "Amino Resins". The difference in page lengths is a reflexion of the efficient cross-reference system where, for example, "A-Stage" resins are dealt with in the articles dealing with the various types of resin.

These reviews can bring one from a vague background to a good general knowledge of the topics dealt with. Supplemented by the bibliographies with each article, one has enough literature background for starting original work. It so happened that I was able to test this out on a real case since antistatic agents and antiozonants are new subjects of interest to my laboratories. The articles in the *Encyclopedia* were very timely.

The articles would probably continue to serve this purpose for perhaps five years in this rapidly expanding phase of polymer work. No doubt Interscience Publishers look forward with pleasurable anticipation to the *Encyclopedia* being rather like the Forth Bridge.

The claim to cover both science and technology is met by the contents of this volume. The authors are mainly senior scientists in the industrial laboratories in the United States, where much of the fundamental science is going on and where so little opportunity for exploitation is lost. The articles vary greatly in the proportions of science and technology and have a heartening attitude not to make any artificial separation of them. Subjects such as "Amino Resins" and "Aqueous Polymerisation" are mainly organic chemistry while "Bag Molding" and "Calendering" are predominantly production technology.

Librarians serving polymer laboratories and the larger science laboratories will wish to purchase these volumes. Apart from being very handsome and beautifully produced editions for the libraries, they will be among the books most frequently not on the shelves. The integration of the fundamentals with their application should be of particular value to teachers in the polymer field, from their own experience being familiar with only some of the aspects of the subject, and to students in gaining a foretaste of the best industrial attitude.

W. F. Watson

Complement

Edited by G. E. W. Wolstenholme and Julie Knight. (Ciba Foundation Symposium.) Pp. xiii+388. (London: J. and A. Churchill, Ltd., 1965.) 60*s*.

IN 1948 Heidelberger and Mayer wrote: "It is happily a rare thing to find in scientific literature a vast body of writings so confused and so mutually contradictory as those on the manifold activities of complement". Since then, the literature on complement has become even vaster, and the symposium held in May 1964, under the auspices of the Ciba Foundation, served a most useful purpose in charting the position of research into some of the many processes in which complement plays a part.

Probably most of the work on complement has been directed to unravelling the complicated process of immune haemolysis, because this system lends itself to precise quantitative experimentation. Information gained from such studies about the many components of complement and their eventual characterization will find applications in the investigation of the action of complement in other immune processes which may be of more immediate value to the organism.

The opening paper by Mayer reviews present-day concepts of the mechanism of immune haemolysis and shows the complicated stages through which a red cell passes before its haemoglobin is finally liberated and it becomes a 'ghost'. A beautifully illustrated paper on electron-microscope studies of lysed cells complements this and shows the actual holes through which the haemoglobin presumably leaks out of the cell. Other papers in this field are on small molecular weight inhibitors of complement, and, perhaps of more interest to clinicians, on haemolytic processes *in vivo* and on the paroxysmal haemoglobinuria red cell. Of more general immunological interest are the contributions on the role of complement in bacteriolysis and phagocytic activity, immune adherence and conglutination and on the site of formation of complement components.

This symposium provides a very useful and up-to-date survey of present-day ideas on many aspects of complement activity. It is well produced and has a good index. A welcome feature is the very full reporting of the discussions which each paper generated; these add greatly to the interest and value of the papers themselves.

A. E. Wilkinson

Light: Physical and Biological Action

By Howard H. Selinger and William D. McElroy. (Monograph Series on Radiation Biology.) Pp. xi+417. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 96*s*.

LIGHT: Physical and Biological Action is one of a number of volumes designed to further the reciprocal exchange of information between the physical and biological sciences, according to the foreword by the director of this series. And it is bound to serve this function well. For this very reason, I do not think that it is particularly suited to the needs of the general student of biology with a smattering interest in photobiology, though, by picking and choosing, he may find much to interest him.

The authors have performed the service of putting together data from various fields and sources, and arranging them in tabular form, ready for use at a moment's notice. The first chapter, entitled "Measurement and Characterization of Light", is filled with tables, and six appendixes summarize the relevant physical constants and conversion factors, as well as filter data, methods for measuring light intensity, the use of firefly luminescence as an assay for ATP, and the theory and availability of various lasers.

The main text is divided into four chapters: Chapter 2, "Excitation of Molecules by Light"; Chapter 3, "Chemiluminescence—Reactions and Mechanisms"; Chapter 4, "Bioluminescence—Enzyme-catalysed Chemiluminescence"; and Chapter 5, "Biological Action of Light".

Chapter 2 is a lucid introduction to modern photochemistry and presents data in useful schematic and tabular form. Chapters 3 and 4, in which the authors are writing out of their own experience, to my mind constitute the main intellectual contribution of the book. Chapter 5 touches on such diverse topics as the anatomy of biological photoreceptors, the mechanisms of plant photosynthesis and phototropisms, vision, killing by radiation, photoreactivation, and others. Because of its breadth and the greater distance of the authors from many of the fields it touches on, this chapter is more uneven than the others. It is, however, amply supplied with references to guide the interested reader to the original literature in each of these spheres.

Ruth Hubbard

STRUCTURE OF DEOXYMYOGLOBIN: A CRYSTALLOGRAPHIC STUDY

By Dr. C. L. NOBBS, Dr. H. C. WATSON and Dr. J. C. KENDREW, C.B.E., F.R.S.
Medical Research Council Laboratory of Molecular Biology, Cambridge

THE results described in this article demonstrate that in deoxymyoglobin the iron atom is 5-co-ordinated; there is no water molecule or other group at the sixth co-ordination position as in ferrimyoglobin. They also show that, at least within the limits imposed by a study at 2·8 Å resolution, the conformation of deoxymyoglobin is the same as that of ferrimyoglobin.

X-ray studies of sperm-whale[1] myoglobin and of horse haemoglobin[2] have made it possible to describe the structures of these two proteins in detail. In myoglobin the analysis has now been extended to include all X-ray reflexions with spacings greater than about 1·4 Å (ref. 3), and this, together with the final elucidation of the amino-acid sequence (Edmundson[4]), has led to a nearly complete picture, atom by atom, of the whole molecule. In haemoglobin the analysis has not yet been carried beyond the reflexions of 5·5 Å spacing, but the low-resolution picture of the molecule thus obtained has shown that its four sub-units each bear a very close resemblance to the myoglobin molecule, and this, together with a complete knowledge of the amino-acid sequences of horse haemoglobin[5,6], has made possible the construction of an atomic model[7] which, while admittedly speculative in some details, must certainly be correct in all its main features. The way is now open to investigate the molecular basis of the physiological functions of the two proteins, their reversible combination with oxygen, and, in haemoglobin, the haem–haem interactions and other well-known phenomena such as the Bohr effect. Indeed, the oxygenation reaction has already been shown to be accompanied in haemoglobin by a gross change in the relative positions of the four sub-units[8]. The present resolution of the haemoglobin Fourier synthesis is, however, insufficient to show whether the conformations of the individual sub-units become changed in detail during oxygenation, though it is certain that if there are changes they must be small ones; nor can it reveal the mode of attachment of the oxygen molecules to the haem groups.

In myoglobin, on the other hand, the high resolution of the Fourier synthesis would be sufficient to reveal detailed changes in conformation (if they occur) and to investigate the nature of the iron-oxygen binding. Even though myoglobin does not exhibit the same complexity of behaviour as haemoglobin, it is clear from spectral and other comparisons that the mechanism of the oxygen binding itself must be very similar in the two proteins, so conclusions reached about the one must also apply to the other.

The main studies of myoglobin have been carried out with ferrimyoglobin (met-myoglobin) at about *p*H 6·8, and have shown that in this derivative a water molecule is attached to the iron atom, in the sixth co-ordination position. Similar methods might be used to determine independently the complete structures of deoxy- and oxy-myoglobins, which are the two forms directly concerned in the oxygenation reaction. Recent investigations[9] of yet another derivative, myoglobin azide, have shown, however, that useful results can be obtained by a much more rapid method, that of the difference-Fourier synthesis. In this method a Fourier synthesis is computed using as its terms the differences between the amplitudes of the reflexions from the derivative and from the native protein, associated with the phases characteristic of the native protein. To a good approximation the resulting synthesis shows as its only features differences in structure between derivative and native structure, in the form of positive peaks if additional atoms have been introduced, and of negative peaks if atoms have been removed. In the present study a three-dimensional difference Fourier synthesis has been used to investigate the differences in structure between deoxymyoglobin and ferrimyoglobin of sperm whale, and hence to draw conclusions about the structure of the former.

Experimental

Deoxymyoglobin is very easily oxidized *in vitro* to the ferric form, especially in the concentrated salt solutions required for crystallization. The main difficulty in the present investigation was to prevent oxidation during the preparation of crystals and their subsequent exposure to the X-ray beam.

Ferrimyoglobin was prepared from sperm whale meat and purified by the method described by Kendrew and Parrish[10]. The solution used for crystallization consisted of saturated ammonium sulphate mixed with 5 per cent by volume of 4 M mixed phosphate buffer (K_2HPO_4 and NaH_2PO_4) at a *p*H of 5·6–5·8 in the final crystallizing solution, and solid ethylenediaminetetraacetic acid to a concentration of 0·01 M to eliminate metal ions which might catalyse oxidation processes. This solution was carefully added to samples of a concentrated salt-free solution of ferrimyoglobin (at least 5 mM) until the mixture was slightly turbid; a fifty-fold excess of solid sodium dithionite (see following) was then added. These additions were made, and crystallization subsequently took place in an atmosphere of nitrogen (containing traces of hydrogen). Diamond-shaped crystals up to 5 × 3 × 1 mm were formed in about a week, and the *p*H of the solution was then adjusted to 6·3–6·4 (that used in X-ray studies of haemoglobin).

For X-ray photography, crystals about 0·6 × 0·4 × 0·1 mm were mounted in sealed quartz capillary tubes containing a drop of mother liquor and a nitrogen atmosphere. A microscope with a hand spectroscope replacing the eyepiece was used for observation of the absorption spectrum of mounted crystals both before and after the X-ray exposure; control experiments with solutions indicated that this technique could detect some 25 per cent of oxy- or ferri-myoglobin in the presence of deoxymyoglobin. During irradiation, oxidation (but not oxygenation) was liable to occur, and to prevent detectable changes in the spectrum during a normal exposure (12 h) it was found necessary to use a fifty-fold excess of sodium dithionite. Data from crystals showing any detectable change in spectrum were discarded.

In contrast to haemoglobin, but in agreement with earlier studies of myoglobin[11], crystals of deoxymyoglobin were found to be isomorphous with those of ferrimyoglobin, the cell dimensions agreeing within 1 per cent. Conventional methods, using the Buerger precession camera and copper $K\alpha$ radiation from a rotating anode X-ray tube, were utilized for recording photographically all reflexions with spacings greater than 2·8 Å. The intensities were measured using a Joyce–Loebl automatic recording densitometer and corrected by the usual factors and placed on an absolute scale by comparison with standard data for ferrimyoglobin. A total of 3,212 reflexions were used to calculate a three-dimensional difference Fourier synthesis: the mean amplitude of the reflexions was 266 electrons, the mean amplitude difference $\overline{||F_{deoxy}| - |F_{ferri}||}$ was 24 electrons and the largest difference 135 electrons.

Results

The most striking characteristic of the difference Fourier synthesis (Fig. 1) is its almost complete lack of features; for the most part it is completely devoid of detail, and it

Table 1. Significant Peaks in the Difference Fourier Synthesis between Deoxy- and Ferri-myoglobin

Peak No.	Co-ordinates (fractional) x	y	z	Maximum excess density (el. Å^{-3})	Location
1	0·38	0·06	0·27	−0·68	At site of sulphate ion near N_δ of *E*7(His)
2	0·28	0·89	0·15	−0·42	At site of haem-linked water molecule
3	0·40	0·42	0·48	+0·32	At site of $AuCl_4^{2-}$ substitution
4	0·28	0·26	0·15	+0·25	At site of *p*-chloromercuribenzene sulphonate substitution
5	0·24	0·89	0·17	+0·24	Between haem Fe and N_ε of *F*8(His)
6	0·07	0·75	0·54	−0·26	Near *EF*4(His) and *EF*3(Gly)
7	0·12	0·72	0·73	−0·21	Near *EF*4(His)
8	0·07	0·74	0·88	+0·20	Near *G*1(Pro), *G*2(Ile), *HC*4(Gln) and HC5(Gly)
9	0·29	0·20	0·29	+0·20	Near *G*17(His) and *H*4(Gln)

contains very few difference peaks which appear to be significant. The standard deviation of the electron density differences, taken over all points in the unit cell, is only 0·06 el. Å^{-3}. We have considered that any peak exceeding three times this value, namely, 0·18 el. Å^{-3} or more, is probably significant; there are only nine such peaks, which are listed in Table 1.

Peak 1. The largest difference peak, a negative one of −0·68 el. Å^{-3}, occurs at the site of a positive peak in the ferrimyoglobin structure near N_δ of the imidazole ring of the 'distal' histidine *E*7. The latter peak is paralleled by a negative difference peak of nearly the same depth (−0·75 el. Å^{-3}) and at the same place in the difference synthesis of azide myoglobin[9]. This difference peak was interpreted as being due to the partial loss of a negative ion, for example, sulphate, when a negatively charged azide group replaces water in forming azide myoglobin; we interpret the negative peak in the present synthesis in exactly the same way, as representing the loss of the negative ion from N_δ of histidine *E*7 during conversion of ferrimyoglobin to deoxymyoglobin.

Peak 2. The next largest difference peak, of −0·42 el. Å^{-3}, is exactly at the site of the peak in the ferrimyoglobin Fourier synthesis which is interpreted as a water molecule attached to the iron atom at its sixth co-ordination position. In the azide derivative this water molecule is replaced by N_3^-; the net addition of two atoms excluding hydrogens (three nitrogens added, one oxygen removed) gave a positive difference peak of +0·75 el. Å^{-3}. In the present case a negative peak of −0·42 el. Å^{-3}, half the absolute magnitude of the former peak within our limits of accuracy, must correspond to the removal of a single atom. The conclusion is inescapable, that during the formation of deoxymyoglobin from ferrimyoglobin the haem-linked water molecule is lost, and nothing takes its place.

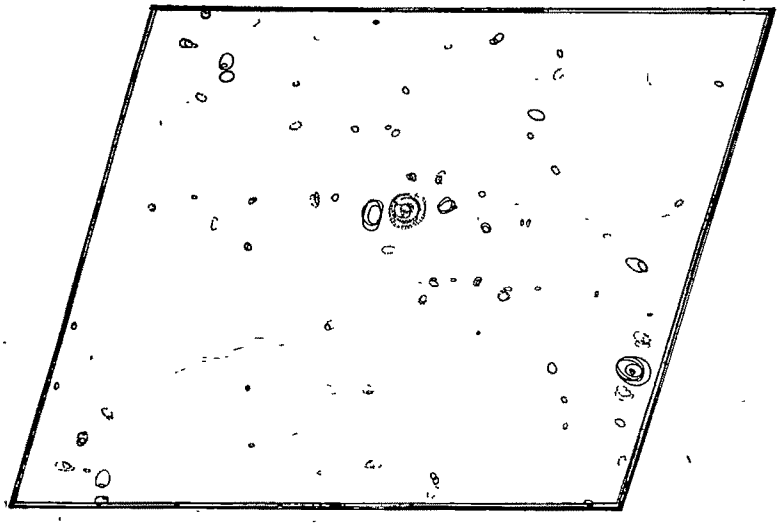

Fig. 1. Slice through the difference Fourier synthesis perpendicular to (010) and lying between $y = 0{\cdot}85$ and $y = 0{\cdot}94$; x axis horizontal. Contours are drawn at multiples of 0·125 el. Å^{-3}, full lines positive and dashed lines negative. The large negative peak in the upper centre is at the site vacated by the haem-linked molecule (peak 2 in Table 1); to its left is the positive peak near the iron atom (peak 5). Near the right-hand edge of the slice is the peak at the gold site (peak 3)

Peaks 3 *and* 4. The next two difference peaks, of +0·32 and +0·25 el. Å^{-3}, are respectively at the site of the gold atom in the aurichloride derivative, and of the mercury atom in the *p*-chloromercuribenzene sulphonate derivative, used for phase determination by isomorphous replacement[12]. Disturbances are found to occur at the heavy atom sites in the ferrimyoglobin Fourier synthesis, and were presumed to be due to residual errors in phase determination. The difference peaks at these sites in the present synthesis may be assumed to have a similar origin, and to be without structural significance.

Peak 5. This small peak lies between the iron atom of the haem group and the N_ε of the haem-linked histidine, 1·6 Å from the former and 1·9 Å from the latter, but displaced 1·4 Å from the line joining these two atoms. While an actual shift of the iron atom cannot be excluded as the cause of this peak[13], its position relative to the haem group and the lack of a complementary negative peak make this extremely unlikely. We prefer to assume that this peak is produced by errors in either the original phase information or in the present measurements.

Peaks 6 *to* 9. These peaks, the only others significantly above the background, all lie outside the boundaries of the molecule. They are all small, and it is not possible to give any precise interpretation of them. They may well represent slight changes in the distribution of water or ions bound to the protein, due to differences in the crystallization medium used in preparing deoxymyoglobin crystals in the present experiments.

Discussion

The almost complete absence of features in the difference Fourier synthesis (apart from the immediate neighbourhood of the iron atom) indicates that the structure of deoxymyoglobin is extremely similar to that of ferrimyoglobin; there is no evidence of conformational changes or of movements of the haem group. It should be noted, however, that slight changes in the orientation of isolated groups would be undetected; some side-chains are partly invisible in the ferrimyoglobin Fourier synthesis (presumably because their conformations are variable), but even in a well-resolved one some degree of rotation would not be detected at the present resolution—for example, it is improbable that at the resolution of 2·8 Å used in the present investigation, we could detect with confidence a rotation of as much as 45° about the Cα—Cβ bond of serine, though movements of more bulky side-chains such as leucine or phenylalanine would be readily visible. No such movements have been observed. Incidentally, it may be noted that the conformation of the molecule has been preserved unchanged within these limits, in spite of the use of a very large excess of sodium dithionite in preparing deoxymyoglobin crystals; this is possibly because any molecules damaged by this reagent were selectively excluded by the process of crystallization.

The most striking conclusion to be derived from the present results is that in deoxymyoglobin the iron atom is 5-co-ordinated; there is no water molecule or other group attached in a sixth co-ordination position as in ferrimyoglobin. We have already indicated that the same must surely be true of deoxyhaemoglobin. In this respect deoxymyoglobin and deoxyhaemoglobin differ from all the other derivatives. Though the absence of a sixth group might be thought to be the most natural explanation of the many unique properties of the deoxy form, especially its paramagnetism[14], and though a structure of this kind was proposed by Pauling[15], it has generally been supposed that a water molecule was present ever since the

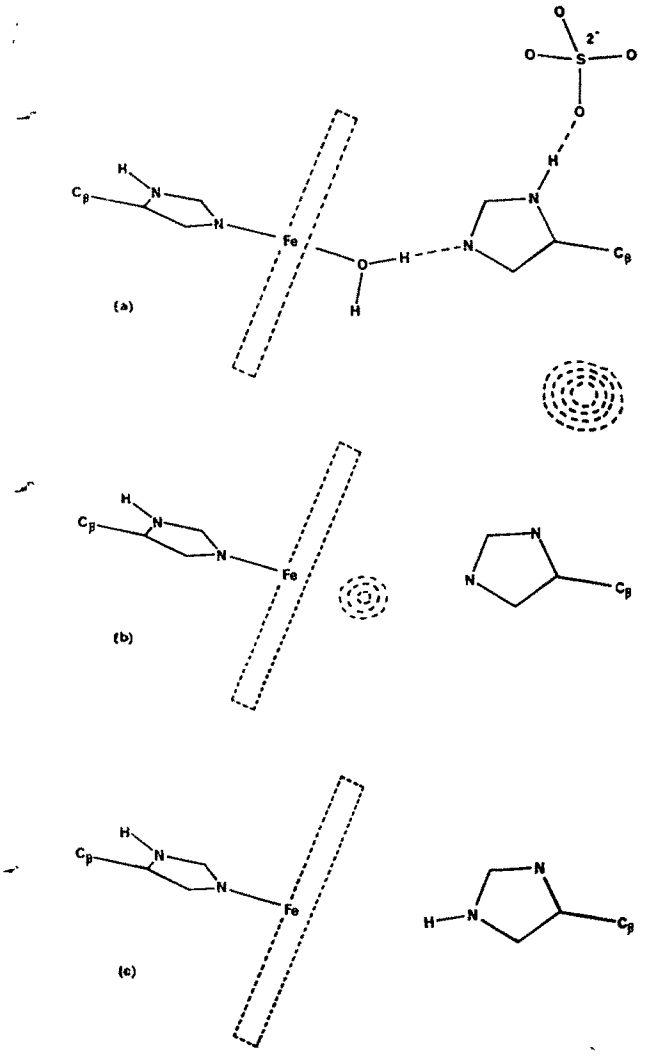

Fig. 2. Schematic representation of the environment of the iron atom in myoglobin derivatives; (*a*) ferrimyoglobin, (*b*) observed negative peaks in difference Fourier synthesis, (*c*) deoxymyoglobin

publication of Haurowitz's ingenious experiments on the spectral changes induced by thorough drying[16].

No evidence can be found from our difference synthesis of any shifts in the position of the iron atom, the haem group, or either of the associated histidine residues *E*7 and *F*8 (quite small shifts of a few tenths of an Angstrom unit should have been detectable). It follows that the environment of the iron atom is the same, apart from the missing water molecule, in deoxymyoglobin as it is in ferrimyoglobin, and in turn the environment in the latter is within the limits of error identical with that in α-chlorohaemin, the crystal structure of which has been accurately determined by Koenig[17].

We have noted the ejection of a sulphate or other ion from its position bonded to N_δ of the distal histidine residue *E*7, as also occurs in the formation of azide myoglobin from ferrimyoglobin. This ion has no physiological significance (the sulphate concentration in a myoglobin crystal has the quite non-physiological value of about 4 M): but its presence or absence is certainly indicative of the distribution of charge around the imidazole ring of the histidine residue. In azide myoglobin its ejection indicated that N_δ has become more negative, and N_ε more positive, in consequence of the introduction of the negatively charged N_3^- in place of a neutral water molecule. In the present case it is the iron atom itself which becomes less positive, that is to say, more negative, in consequence of being reduced from ferric to ferrous, and the result is the same. Our interpretation of the changes which occur is shown schematically in Fig. 2.

Finally, these results show that under good conditions it is possible to detect the loss of a single oxygen atom from a protein molecule, without going through the lengthy process of a complete structure determination of the derivative under examination. Provided that the structure of the parent substance has been determined to a resolution of 2 Å or better, and provided that the derivative is isomorphous with it, the technique of difference Fourier synthesis should be capable of elucidating the details of interactions between proteins and small molecules such as enzyme substrates, inhibitors and coenzymes. It should be a valuable tool for the investigation of the detailed mechanism of enzyme reactions.

We thank Miss Eva Rowland and Mr. M. Fletcher for able technical assistance. One of us (C. L. N.) thanks Shell Oil (New Zealand), Ltd., for the award of a Shell postgraduate scholarship, Mr. C. J. Mackay of Shell International Petroleum Co. (London), Ltd., for his interest and encouragement, and the Rockefeller Foundation for a grant.

This work was first reported by one of us (J. C. K.) at the Cambridge meeting of the British Biophysical Society, April 1965.

PERMANENCY OF THE CONTINENTS

By JEROME B. CARR
Sperry Rand Research Center, North Road, Sudbury, Massachusetts

EITHER the continents have moved relative to one another or they have stayed generally in one position. The theories relating to these opposed views are known, respectively, as 'continental drift' and the 'permanency of continents'. Early evidence which led to the development of the theory of continental drift was the apparent similarity of the east coast-line of South America and the west coast-line of Africa. However, the theory of continental drift does not offer a unique explanation of the similarities of the two coast-lines and the associated Mid-Atlantic Ridge. A second explanation of the similarities may be derived from the theory of permanency of continents when combined with a world-wide shear pattern such as developed by Vening Meinesz in 1947 (ref. 1).

The purpose of this article is to evaluate Vening Meinesz's crustal shear pattern on a world-wide basis.

It not only presents evidence regarding the relative strength of the two opposing theories, but also offers the first explanation of the world-wide heat-flow data (heat flow through the crust). Information is also included that will be of importance in developing an optimum technique for mapping ocean bottom topography.

Origin of the Shear Pattern

Vening Meinesz[1], after investigating the results of the then new method of ocean bottom mapping by echo sounding, noticed more or less regular linear topographic patterns, mostly in two directions, over extended parts of ocean floors. He associated this work with the shear plane evidence brought out by the old 'lineament' tectonicians. Since there was an apparent world-wide distribution of shear planes, Vening Meinesz thought it likely that there was a world-wide cause responsible for the development of a world-wide shear pattern as opposed to a world-wide distribution of random shears.

Vening Meinesz investigated stresses in the Earth's crust brought about by a shift of the crust with respect to the axis of rotation. The basic theory is that the Earth rotates about an axis, and is flattened at the poles and bulges at the equator. If the Earth's crust were to be shifted, *in toto*, the new crust at the poles would become flattened and the new crust at the equator would bulge outwards. Such a change in the relative shape of the crust would produce stresses in the Earth's crust, and these stresses, if great enough, would cause a 'breaking' or 'cracking' of the crust; in other words, a shear pattern would develop.

Mathematical shear patterns were obtained by Vening Meinesz for various shifts in the Earth's crust relative to the axis of rotation and by considering changes in the Earth's shape caused by changes in the speed of rotation. The pattern which most closely matches the topographic features of the Earth is shown in Fig. 1. This is the shear pattern that would develop if the Earth's crust shifted relative to the axis of rotation for a distance of 70° along a line 90° E. from the prime meridian. That is, the north pole of rotation makes an apparent shift 70° along the line 90° E., and the south pole makes an apparent shift 70° along the line 90° W. into their present positions. Note that the axis of rotation must remain fixed in space and it is the crust that shifts.

The postulated cause of this shift in the Earth's crust is either convection currents in the Pre-Cambrian acting directly on the crust itself, or else redistribution of mass (continental growth) associated with these Pre-Cambrian convection currents. This latter mechanism is very simple to picture. Imagine a child's top rotating about a vertical axis. Now, if a lump of clay is added to the exterior portion of the top, or if a piece of the top is removed, then it is easily seen that on rotation the top still possesses its vertical axis but the mass of the top now re-aligns itself with respect to the axis.

It should be noted that the postulated convection currents are not the convection currents existing at present, but Pre-Cambrian convection currents. Jeffreys[2] directs attention to the difficulties of maintaining convection in the Earth as we know it to-day, but he also points out that convection seems to be likely during a certain stage in solidification of the Earth. As this article is intended to examine the postulated shear pattern and not the mechanism behind, it, the reader is referred elsewhere for further discussion of convection in the mantle[1–3].

Comparison of the Shear Pattern with Ocean Bottom Topography

To evaluate the shear pattern shown in Fig. 1, two maps were used. The first map, entitled *The World*, was published by the U.S. Navy Hydrographic Office at a scale of 1 : 12,233,000 at the equator. This map measures 8 × 12 ft. and presents the bottom topography of the Indian, Atlantic and Pacific oceans as it was known in 1961. The second map, prepared by the University of Wisconsin, entitled *Bathymetric Chart of the Arctic Basin*, was used for evaluation of the topography of the Arctic Ocean[4]. These maps allow extension of the original work into areas not previously examined with respect to the shear pattern. The new maps increase coverage so that all the floor of the ocean is now evaluated instead of only the portion outlined in the original study. This means

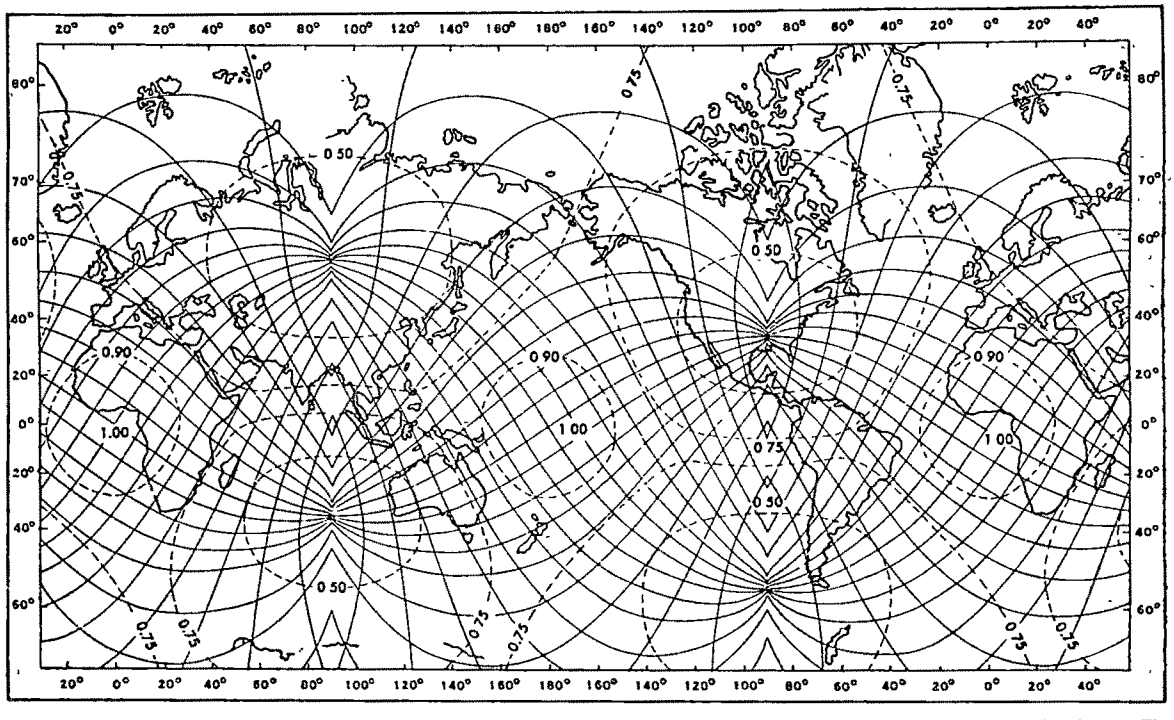

Fig. 1. Theoretical shear pattern in Mercator's projection for an apparent shift of the poles over 70° along the meridian of 90° longitude. The solid lines show the expected directions of shear and the dashed lines show the relative shear intensity which reaches a minimum where the shear pattern concentrates and a maximum in the areas labelled '1·00'

that the coverage of the Earth is increased from 50 per cent to 70 per cent. This figure of 70 per cent will be raised later in this article as some structures of the Canadian Shield and almost all of Africa are also evaluated.

Secondly, these new maps contain many data that were not available during the original investigation. Examples of large tectonic features, that are not in evidence on the original maps evaluated, are: (1) the Chile Rise; (2) the portions of the mid-ocean ridges south of Africa and Australia; (3) the Emperor Seamount Chain; (4) the Mendocino Seascarp; (5) the Murry Fracture Zone; (6) the deep trench located at 44° N., 174° W. Not only were these new features delineated but also the previously known features are more accurately defined and substructures are now apparent in many cases.

At the start of this investigation, the azimuths (measured in degrees east or west of geographic north) of all major oceanic structures were determined and compared with the corresponding azimuths of the theoretical shear pattern at the location being evaluated. Data points were taken approximately every 300 miles: (1) along borders of continents; (2) along island arcs; (3) along ocean trenches; (4) along the world-wide system of mid-ocean ridges; (5) along major fault structures; (6) along island chains; (7) along sea mount chains. The only areas of the world excluded were the borders of Antarctica (but the Palmer Peninsula was included) and the ocean areas inside the Sea of Okhotsk and the Sea of Japan. These latter areas were excluded because Japan, the Kuril Islands, and Kamchatka were taken to be the eastern border of Asia rather than the Chinese mainland.

The frequency distributions for the two sets of azimuths are shown in Figs. 2 and 3. The fact that the ocean structures fail to show a random azimuthal distribution reinforces the basic concept of a world-wide control of tectonic features. A comparison of the two curves shows that the distribution of the Earth's features does not exactly follow the predicted shear patterns. This is to be expected for four reasons: (1) the Earth's crust was probably not homogeneous and isotropic at the time of the generation of the shear pattern (for example, there may have already been some continental growth); (2) the sampling of the world used in this investigation was restricted to ocean areas, and the ocean basins are not symmetric about the Earth; (3) the theoretical shear pattern is not symmetric about the poles because the

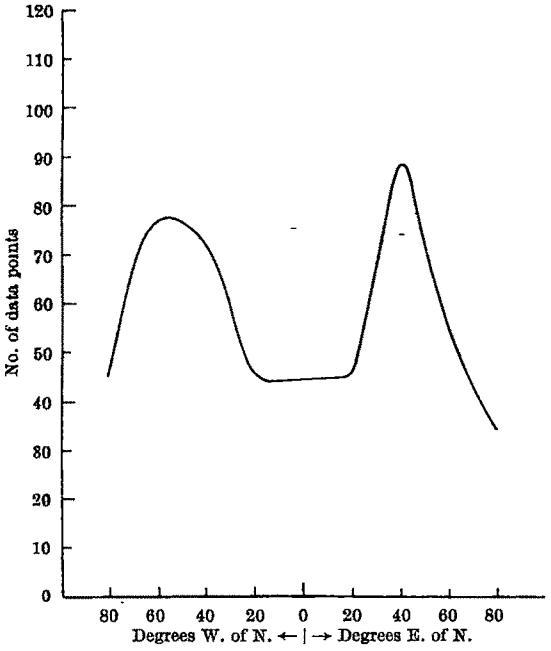

Fig 2. Azimuthal frequency distribution of the Earth's oceanic features

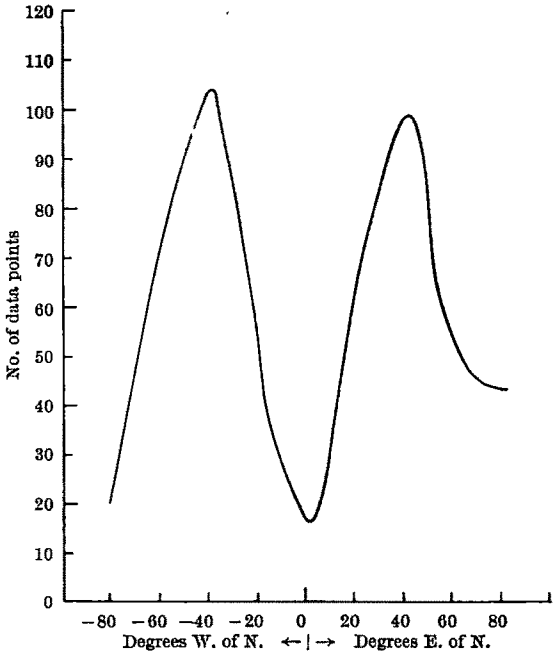

Fig. 3. Azimuthal frequency distribution of the theoretical shear pattern; that is, frequency distribution of the direction of expected shear at all locations of observed ocean bottom features. Note that the frequency distribution shown in Fig. 2 is a damped model of the foregoing frequency distribution

postulated change in axis of rotation is 70° and not a convenient 90°; (4) the local stresses applied to the Earth's crust at any time before the time of shearing should offer zones of weakness in random directions, which would modify the expected shear pattern or which would be co-existent with the shear pattern and tend to 'damp out' the peaks and troughs of the frequency distribution. Also, local stresses applied to the Earth's crust after the shear pattern has developed may not be able to 'take advantage' of the pre-existing zones of weakness and therefore may generate new lines of shear independent of the world-wide 'caused' shear pattern. These new lines of shear will also act to 'damp out' the effects of any world-wide cause of crustal shearing.

Notwithstanding all these difficulties, the remarkable similarity of the two frequency distributions suggests that serious consideration should be given to further investigation of Vening Meinesz's crustal shear pattern.

After comparing frequency distributions of the topography and the theoretical shear pattern, correlation coefficients between the observed azimuths and the theoretical azimuths were computed. The resulting correlation coefficients are presented in Table 1. Four important points should be noticed: (1) that more than 50 per cent of the correlation coefficients are greater than 0·90 and that 90 per cent are greater than 0·80; (2) that both areas where correlation reaches 0·94 are located in

Table 1. Correlation Coefficients as computed between the Theoretical Shear Patterns and the Ocean-bottom Topography and Continental Borders

Structures in the Indian Ocean excluding its borders	0·87
Structures in the Atlantic Ocean excluding its borders	0·94
Structures in the Pacific Ocean excluding its borders	0·90
Southern border of Asia	0·92
All structures in the Caribbean Sea, including the border of the Gulf of Mexico	0·92
North America excluding Arctic Ocean	0·92
Border of Arctic Ocean and its internal structure	0·78
Atlantic coast of South America	0·94
Pacific coast of South America	0·80
Mediterranean Sea area	0·92
South American border *in toto*	0·91
African borders excluding Mediterranean area	0·87
European border excluding Arctic Ocean borders	0·87
All major island arcs regardless of location	0·90
Australia, excluding northern border	0·91
Borders of the Indian Ocean	0·68
Pacific Ocean border excluding Asia	0·86
Indonesia, entire area, all island chains, etc.	0·89
Atlantic Ocean boundaries	0·90
Average world-wide correlation (average of above figures)	0·88

the Atlantic Ocean and on the Atlantic Coast of South America; (3) that the lowest correlation is located around the Indian Ocean; (4) that the last-mentioned two areas are predicted to have, respectively, high and low relative shear intensity by the dashed lines in Fig. 1. Thus, the theory behind Vening Meinesz's crustal shear pattern not only predicts the directions that most of the large-scale features will take but also predicts where correlation will be high and where it will be low.

Again, in Table 1, it should be noted how highly the borders of continents correlate with the theoretical shear pattern. This strongly implies that the shear pattern developed before the continents completed their growth. Continental growth (defined as the areal expansion of continents with time) is known to be complete by the start of the Cambrian: Fig. 4 shows North America at this time[5]. There is, in fact, much more evidence that the continents were already completed by Cambrian time, but this one figure will save belabouring the point. (Note it is not suggested that the continents were 'volumetrically' complete. There is ample evidence that new material is being added to the continents from the upper mantle, but it is repeated that the areal extension of continents has remained essentially unchanged since the Cambrian period.)

Since the continents were complete at the start of the Cambrian, and since there is a strong correlation between the borders of continents and the theoretical shear pattern, then it is concluded that the shear pattern developed in the Pre-Cambrian. If this age were correct, and if the shear pattern at present observed on the floor of the ocean were to match the pattern generated by the theoretical model, then continental drift would become a complete impossibility, as any motion of the ocean floor would destroy the correlation between ocean bottom topography and the theoretical shear pattern.

Comparison of the Shear Pattern with Other Geophysical Evidence

Now that it has been established that the shear pattern does indeed correlate well with the ocean bottom topography over the entire world, it becomes worth while to examine the relationship between three parameters that have been evaluated on a world-wide basis. These are: (1) the relative shear intensity of Vening Meinesz's crustal shear pattern (as shown by the dashed lines in Fig. 1); (2) the deviation of the Earth's crust from the theoretical geoid (hereafter referred to as geoid heights); (3) the heat-flow data. (The data for these last-mentioned two parameters were taken from Lee and MacDonald[6].) For all correlations computed in the following paragraphs the same sampling procedure was used to establish the degree of representation and homogeneous treatment of the data.

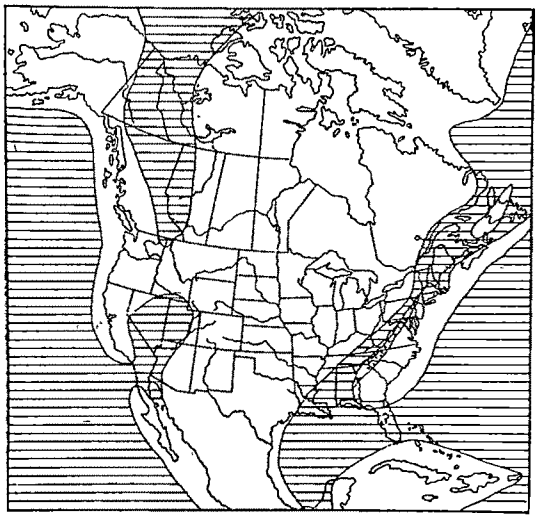

Fig. 4. Generalized palaeogeographic map of early Cambrian of North America. The ruled area shows sea and the clear area shows land. The dotted area was also possibly sea

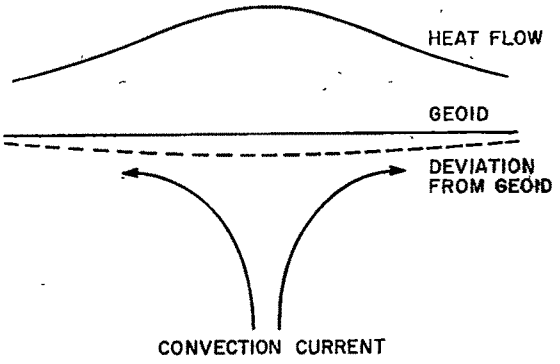

Fig. 5. Relationships between convection currents, heat flow and deviations from the geoid as postulated by the theory of continental drift

First, let us consider the correlation between the geoid heights and the heat-flow data. The heat-flow data, as a whole, show that higher values exist over continental rather than oceanic areas. As these values should reflect any convection currents at present active in the Earth's mantle or lower crust, it appears that convection currents (if they exist to-day) flow in directions opposite to those required by the theory of continental drift. But convection currents, if they exist, should also affect geoid heights. The theory of continental drift postulates that above a rising component of a convection cell the heat flow will be enhanced and the geoid will be depressed (see Fig. 5). For descending components of the convection cells, the opposite is expected. Therefore, one would expect to see a good correlation between the heat-flow values and the geoid heights if convection currents exist to-day. The data show a linear relationship with a correlation coefficient of $-0{\cdot}33$ and with large variance. This relationship is at least of the right sign, but it can only explain 10 per cent of the variability of the heat-flow data and thus most probably indicates only chance relationship.

It is also reasonable to expect a chance relationship between geoid heights and the relative shear intensity, as a mere cracking or breaking of the Earth's crust would not be expected to affect the shape of the geoid. The correlation coefficient between these two parameters was found to be 0·15, which indicates the expected chance relationship.

However, correlation between heat flow and the relative shear intensity is a different matter. The calculation of the correlation coefficient between the relative shear intensity and the heat-flow data gave a result of $-0{\cdot}52$. This figure is an improvement over the $-0{\cdot}33$ computed for the linear relationship between heat flow and geoid heights. However, on plotting the heat-flow data versus the relative shear intensity, it was found that the relationship between these parameters is bi-linear, not linear. In Fig. 6 it is seen that there is no relationship between these two parameters for values of low shear intensity, but that at high values of shear intensity there is a good relationship. The correlation coefficient between these two parameters for values of high-shear intensity is $-0{\cdot}72$, and this means that the variability of high-shear intensity can explain 50 per cent of the variability of low heat-flow data.

In Fig. 7, the two sets of data have been mapped. It should be noted that: (1) the areas of low heat flow coincide with areas of high shear intensity; (2) the heat flow is found to be symmetric about 90°, as is the shear intensity; (3) 90° is the line along which the poles shifted as the generating mechanism for the shear pattern. Thus, even the general pattern and symmetry of the heat-flow

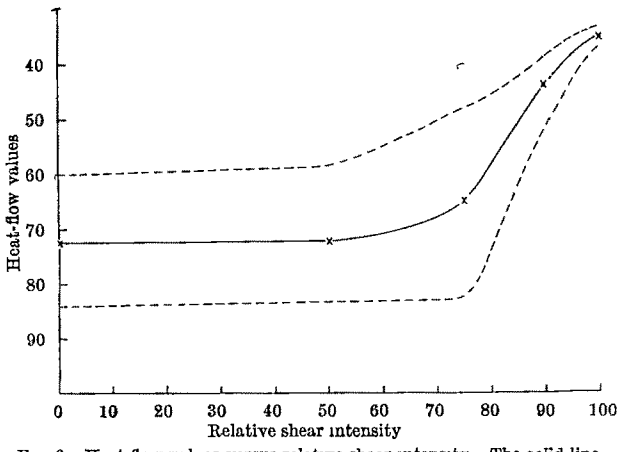

Fig. 6. Heat-flow values versus relative shear intensity. The solid line is drawn through average heat-flow values (denoted by X) and the dashed line represents the envelope enclosing all data points. Note that the solid line could be represented by two linear curves intersecting at the point where the heat flow equals 72 and the relative shear intensity equals 0 65

data reinforce the concept and mechanism of Vening Meinesz's world-wide crustal shear pattern.

Now to explain the negative value of the correlation between the heat flow and the relative shear intensity. Consider an area of high-shear intensity with its corresponding 'breaking' of the Earth's crust. This area offers paths for advection of molten mantle material along the 'zones of weakness' or 'breaks' in the Earth's crust. Thus this area of high shear intensity offers two mechanisms for heat loss: (1) conduction and (2) advection through to the Earth's surface. However, areas of low shear intensity will offer conduction alone or conduction with lesser amounts of heat loss by advection. Since over long periods of time heat has been lost by advection through the crust in areas of high shear intensity, and since heat loss by advection would be smaller in areas of low shear intensity, then obviously the sub-crustal temperature will remain 'higher' in areas of low shear intensity and higher heat-flow values will be observed to-day in those areas of low shear intensity—all other factors being equal. Therefore, there is indeed a reasonable and logical reason for the existing relation between high shear intensity and low heat flow.

Thus the theory of permanency of continents with the associated postulated movement of the axis of rotation not only explains the distribution of features on the ocean bottom and the shapes of the continents, but also offers the first theory for explanation of the gross features of heat flow through the Earth's crust. It should be noted that this is a considerable improvement over the theory of continental drift which requires doubtful convection currents to exist in the Earth's mantle and which requires them to flow 'backwards'.

There is additional evidence supporting the permanency of continents and the theoretical shear pattern. Tatsch[7], using a three-dimensional least-squares analysis, points out that about 93 per cent of all active volcanoes lie along a world-wide system of belts which may be defined approximately by the great circle traces of three mutually orthogonal planes passing through the centre of the Earth. These three planes are symmetric about 90°, as is the shear intensity and the world-wide heat flow.

Now it is seen that the shear pattern correlates well with two independent geophysical parameters, namely, heat flow and distribution of volcanoes. Most of the data for these parameters were gathered and reduced after the theoretical shear pattern was proposed. When one uses this form of 'predictability' or 'later day verification' as a method of comparing theories, then it should be noted that the theoretical shear pattern when combined with the permanency of continents offers a considerable improvement over the theory of continental drift which seems to be 'modified' almost every time some new 'evidence' is uncovered.

Comparison of the Shear Pattern with Continents

North America and Africa are the two continents to be evaluated. Before we go into the actual evaluation, it would be wise to point out a major difference between these two continents. This major difference in the continents is the apparent difference in their growth patterns. North America presents a growth pattern in which new areas of continental growth appear to be added to the

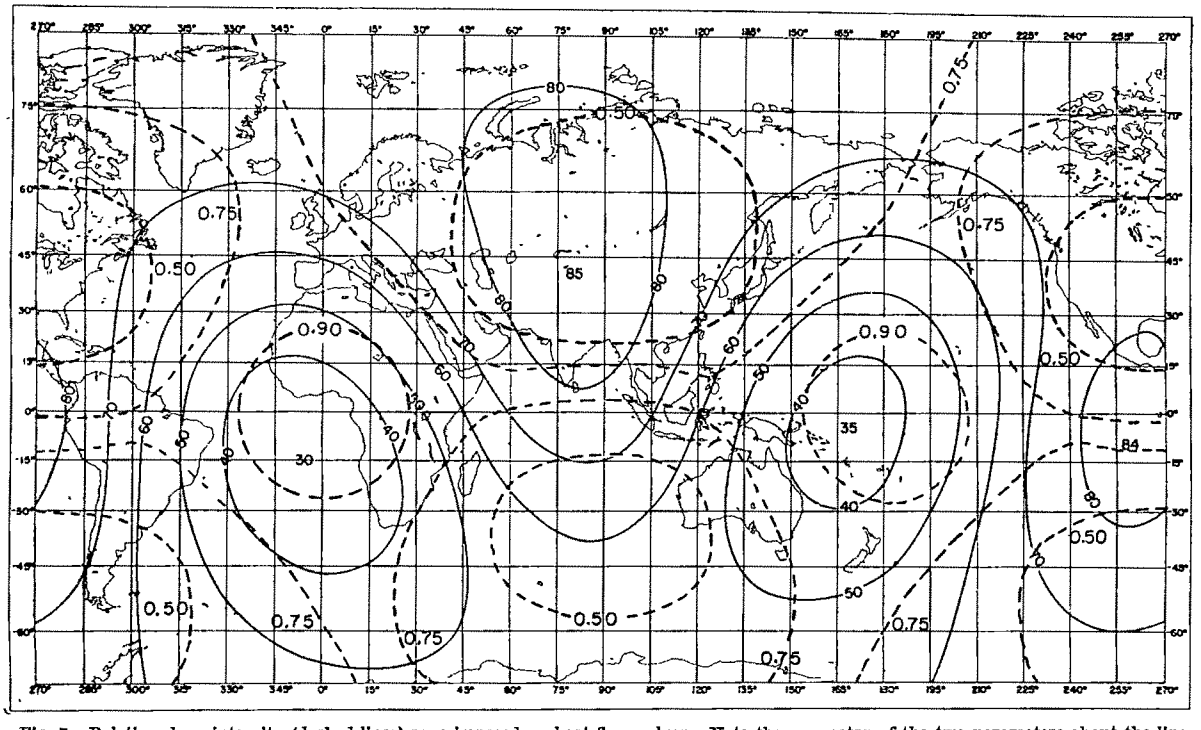

Fig 7. Relative shear intensity (dashed lines) superimposed on heat-flow values. Note the symmetry of the two parameters about the line 90° E. 90° E. is the line along which the north pole made its apparent movement into its present position

borders of the old areas. Thus, North America appears to have grown about some centre or nucleus. Africa, however, presents an entirely different picture. The orogenic patterns in the shield areas of Africa seem to cross one another in an apparently random pattern with no obvious nucleus present. These differences in continental growth patterns have led to some conceptual difficulties between geologists from different areas of the world. If Vening Meinesz's crustal shear pattern can explain some of the obvious differences between the two different continental types, then the shear pattern when combined with the permanency of continents will be helping to solve a problem that continental drift by its very nature will be unable to explain.

Table 2. Average Potassium–Argon Ages from the Dike Swarms as shown and numbered in Figs. 8 and 9

Dike swarm No.	Age in million years	Matches theoretical shear pattern
1	2,485	Yes
2	2,150	No
3	2,165	No
4	2,090	No
5	1,675	No
6	1,230	Yes
7	1,315	Yes
8	1,220	Yes
9	1,030	Yes
10	875	No
11	790	No
12	700	Yes
13	640	No

The data to be evaluated for North America are the distribution of diabase dike swarms of the Canadian Shield[8]. These dike swarms are shown in Figs. 8 and 9, and their isotopic ages are shown in Table 2.

The importance of the results shown in Table 2 is that there is a period from 1,315 million years to 1,030 million years where the correlation between the azimuths of the dikes and the azimuths of the theoretical shear pattern is fairly good. This implies that the shear pattern affected the continental regions as well as the oceanic regions and that the shift of the pole may very well have occurred at, or before, 1,315 million years ago. This evidence, on a different scale of structures from those used to evaluate the oceans, is important and the shear pattern theory is reinforced by the fact that the general trend of the Grenville Province, as shown in Fig. 9, seems to be well controlled by the theoretical shear pattern. Therefore, the shear pattern should have occurred before the development of the Grenville Province (950 million years ago) and more probably before the development of dike swarms, dated 1,315 million years. It is also reasonable to expect that local stresses applied to the Earth's crust after the time of shearing may be able to 'take advantage' of the pre-existing shears. Thus many young geological structures will be found to match the pre-existing shear pattern.

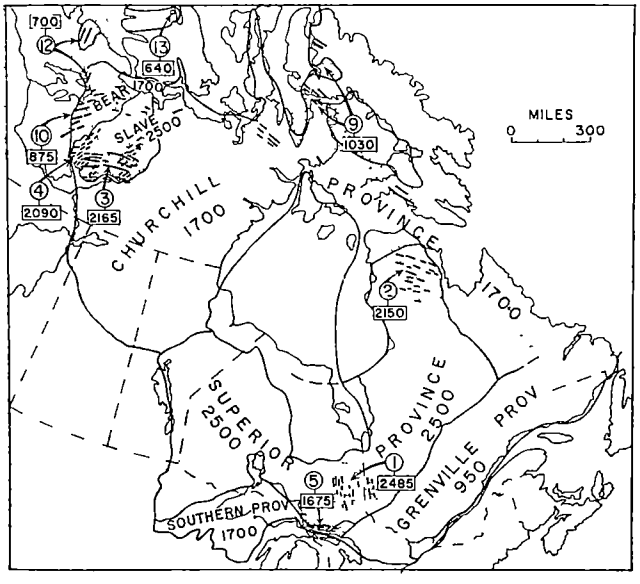

Fig. 8. The diabase dike swarms of the Canadian Shield. These swarms are shown in two figures for the sake of clarity. The geological provinces of the Canadian Shield are outlined by the solid lines and their approximate ages are given (in million years) below the name. The diabase dike swarms are indicated by the arrows pointing to them and the potassium-argon age is indicated in the boxed number below the encircled swarm number

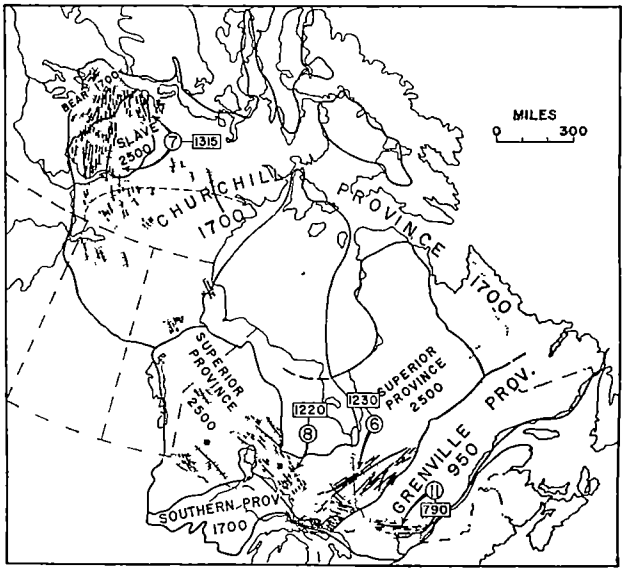

Fig. 9. The diabase dike swarms of the Canadian Shield (continued from Fig. 8)

Now, to test for significance of the foregoing data, consider the azimuth of any random shear. Azimuths of any such shear may be measured from 0° to 90° west of north and from 0° to 90° east of north. Thus a span of 180° will include all possible shears. Any shear the general trend of which is within 10° of the theoretical shear is considered to 'fit' the theoretical shear pattern. It should be borne in mind, however, that in any location it is possible to have two shear directions. Thus the probability of any random shear following the theoretical shear pattern is 2 (10° E. + 10° W.)/180° or 2/9. Treating the azimuths of dikes as a binomial distribution, the probability of six 'fits' out of thirteen dike swarms is 0·032. Since the probability is so low for the six 'fits' that are observed (see Table 2), then quite obviously the azimuths of dikes in North America are not random, but there appears to be an underlying control for many of the dikes and this control appears to be Vening Meinesz's crustal shear pattern.

Note that the North American data show: (1) that the trend of the Grenville Province follows the theoretical

Table 3. Dated Pre-Cambrian Structural Trends of Africa

Structure No	Age in million years	Matches theoretical shear patterns
3	3,400	No
18	2,944	No
8	2,800	Yes
17	2,550	Yes
9	2,250	Yes
4	1,850	Yes
19	1,650	No
7	1,600	Yes
15	1,500	No
16	1,500	Yes
6	1,000	Yes
14	660	Yes
10	625	No

Table 4. Undated Pre-Cambrian or Post-Cambrian Structural Trends of Africa

Structure No.	Age in million years	Matches theoretical shear pattern
1	?	Yes
2	?	No
5	?	Yes
11	?	No
12	?	Yes
13	?	Yes
20	?	No

shear and is dated at 950 million years ago; (2) that there are four 'fits' in a row, which implies the shift of the poles occurred before 1,315 million years ago, and (3) there is one 'fit' dated at 2,485 million years ago. The significance of this 'oldest fit' will be clarified by considering the results obtained from the African data.

The major structural trends for Africa are shown in Fig. 10 (ref. 9). Those structures that have been dated by isotopic means are listed in chronological order in Table 3 and the structures that have not been accurately dated by 1961 are listed in Table 4.

The probability of the twelve 'fits' out of twenty African structures being due to a random process is 0·00022. This makes Africa one continent out of 4,545 (based on a random distribution) while North America is only one continent out of 31. Thus the control exerted by Vening Meinesz's crustal shear pattern in Africa is much greater than is the control in North America. Note that this is predicted by the relative shear intensity (the dashed lines in Fig. 1) of the theoretical shear pattern.

Now, to return to the differences in growth patterns between Africa and North America, we note that (see Fig. 1) the shear pattern in Africa produces a cross-hatch pattern, while in North America the lines of shear converge to a point or are symmetrical about the point of convergence. Thus, if the shear pattern controlled continental growth, we would expect growth about a centre in North America or at least a lack of crossing structure due to the low values of the relative shear intensity. We would also expect Africa to have a very intense cross-hatch structure due to the high relative shear intensity and the nature of the shear pattern in that area. This is exactly what we see in the structure of these continents. Thus, the shear pattern is also capable of explaining the development of two apparent grossly different continental types which have long puzzled geologists. Perhaps when all the continents have been evaluated we shall know which of the two parameters plays the controlling part in continental growth, that is, the direction of shear in the shear pattern or the relative shear intensity.

To find out if that odd fit at 2,485 million years in North America has any significance, let us look at Table 3, which shows that there are 4 fits in a row in Africa starting out at 2,800 million years ago. Thus, it appears that the North American fit at 2,485 million years is not an accident but that the time of occurrence of the re-

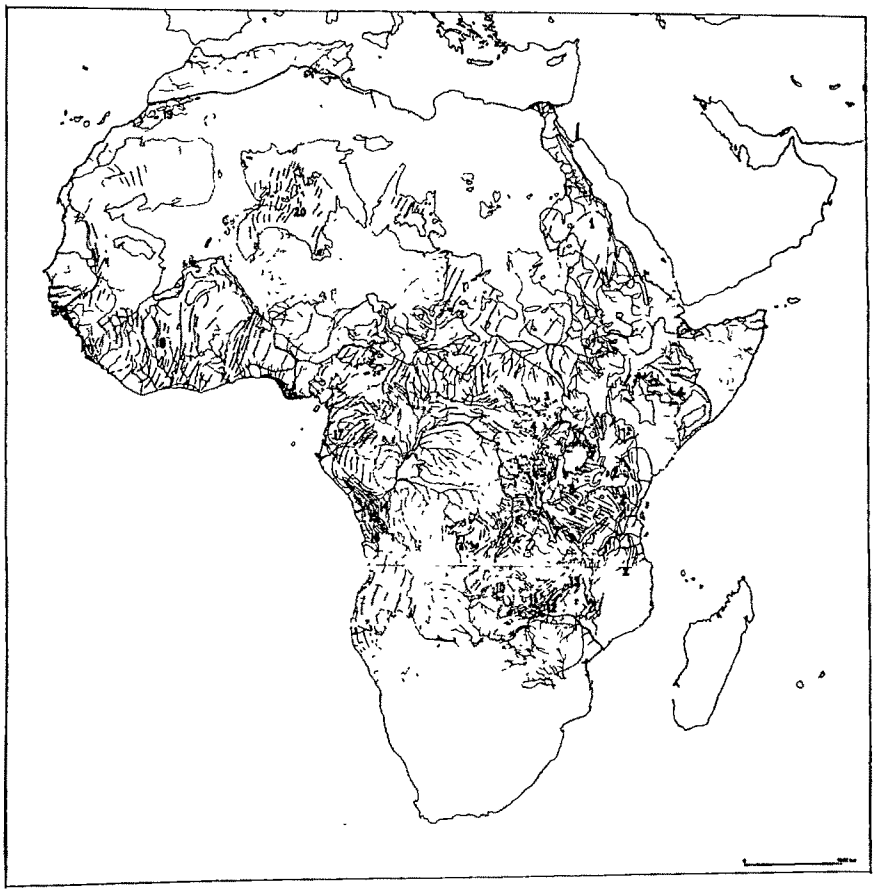

Fig. 10. Structural sketch of middle and northern Africa. In equatorial Africa the trends have been taken chiefly from original documents; in west and northern Africa, from River Furon, *Esquisse structurale provisoire de l'Afrique*, Paris (1959), Assoc. Serv. géol. africains. (1) Egypt and Sudan. Last events of a polycyclic evolution have been dated in Egypt (435–540 m.y.). (2) Mozambique belt. Last events of a possibly polycyclic evolution have been dated (465–636 m.y.). (3) West Nile belt. Considered extremely old; probably older than *c*. 3,400 m.y. (4) Groupe du Kibali. Probably older than *c*. 1,850 m.y. and probably linked with Buganda series to the north of Lake Victoria, which are certainly older than 1,850 m.y. (5) Groupe de l'Urundi and Karagqe Ankolean system, imprecisely dated but in physical continuity with No. 6. (6) Groupe des Kibara. Late orogenic events are dated at 1,000 ± 50 m.y. (7) Ubendian: Groupe de la Ruzizi. Postorogenic phase is dated at *c*. 1,600 m.y. (8) Nyanzian and Kavirondian. Common lead model ages which may date the Nyanzian are *c*. 2,800 m.y. (9) Dodoman. Older than 2,250–2,440 m.y. (10) Katangan belt. Late orogenic uranium mineralization (Shinkolobwe) at 625 m.y., postorogenic uranium mineralization (Zambia) at 500 m.y. (11) Irumi belt, undated, pre-Katanda. (12) Rufunza belt, older than Irumi. (13) Mafingi belt, probably part of the Late Pre-Cambrian–Early Palaeozoic activity. One age *c*. 440 m.y. (14) Groupe du Congo Occidental. Activity at *c*. 660 and *c* 475 m.y. (15) Groupe des Monts de Cristal (Système du Mayumbe); older than *c*. 1,500 m.y (16) So-called Basement of Northern Angola. Some of this belongs to the Système du Mayumbe (see No. 15). Other crystalline rocks are or may be much younger (17) Basement Complex of North Gabon and Southern Cameroons, *c* 2,550 m.y. or older. (18) West Africa; see text. (19) Anti-Atlas-Morocco. One age post-dates the earliest Pre-Cambrian in this area, 1,650 m.y (20) Hoggar. Undated area, generally correlated with the west African section

lative shifting of the poles occurred at least 2,800 million years ago. Confirmation or further pushing back of this date should occur as other continents are evaluated.

The inferences that can be drawn from the results of this research are: (1) That the shear pattern can be used to predict the directions of ocean bottom features that should be discovered in ocean areas so far unexplored. In fact, this is a method of testing the theoretical shear pattern. (2) That because certain directions are expected in ocean bottom mapping, optimum mapping procedures could be developed to uncover fully the ocean bottom topography in any ocean area. The Arctic Ocean will be the most difficult region in which to predict directions of topography (see Table 1). (3) That a drilling operation in a true ocean basin will uncover Pre-Cambrian rocks once the drill has passed through the layer of sediments and lava flows. The ages of these rocks could quite possibly be older than any known continental rocks. Even the finding of early Palaeozoic rocks will weaken the present theory of continental drift, because the theory postulates that the rock of the ocean basins is continually returned to the mantle by convection currents.

It should be noted that some gabbro from St. Paul's rocks on the Mid-Atlantic Ridge has been tentatively dated at 4,500 million years old[10]. Thus a region of an upward component of a convection current postulated by continental drift, which should be a region of very young rocks, possesses rocks which are older than any known continental rock.

In the light of (1) the new ocean bottom data confirming existence of the world-wide shear pattern, (2) the structural data of continental interiors dating the shear pattern as at least 2,800 million years old, and (3) the independent heat-flow data and the distribution of volcanoes reinforcing the generating mechanism of the shear pattern, it is concluded that the majority of the Earth's major topographic and geological features are controlled by, or grew along, major zones of weakness generated as part of the world-wide shear pattern. The preservation of this shear pattern on the ocean bottom for a period of 2,800 million years firmly enforces the theory of the permanency of continents.

OBITUARIES

Dr. P. L. E. Rothschild

Dr. Paul Rothschild, who died on November 11, 1965, was born in Mannheim in 1901 and graduated M.D. at Freiburg in 1926. With the coming of the Nazi régime in 1933 he saw no future for himself in Germany, and moved at once, with his family, to England, and was naturalized in 1938. He obtained a British qualification in 1934 and from then on practised medicine in Britain: in a Welsh mining village (1934–37), in London (1937–42), in the Royal Army Medical Corps (1942–46), and again in London until his death.

It is written in *Ecclesiasticus*: "Honour a physician with the honour due unto him . . . for the Lord hath created him". Paul Rothschild was honoured by all his many patients, not only for his skill and wisdom but also because he knew that the Lord had created them, too, and he treated them so. One of his treasured possessions was a miner's lamp, the one he had used in the pit in his Welsh village when emergency called him. A patient once asked him what he would do if he learnt he would die at 3 p.m. next day. His answer, "I should see my last patient at 2.30", was true; he had known the precarious state of his heart for a long time, but continued to communicate his courage, by work and example, to others.

It was a good many years, after his M.D. in 1926, before he turned over finally to medicine. Two years were spent in a pathological institute in Berlin, then two years with Otto Meyerhof, first at Berlin-Dahlem and later at Heidelberg. That is how I came to know him, and also because of an admirable paper on the physiology of muscle, published in 1930 in the *Biochemische Zeitschrift*. Then he came to England to extend his scientific experience, working with Verney at University College, London, with Barcroft at Cambridge, and with Thomas Lewis and his colleagues at University College Hospital. Between 1927 and 1934 there are sixteen of his published papers referring to all this (published in the *Journal of Physiology*, *Heart*, *The Proceedings of the Royal Society* (B), *Biochemische Zeitschrift*, etc.).

After this scientific pilgrimage to England, Rothschild returned to Germany, as "Assistent" with the late Prof. Volhard at the University Hospital in Frankfurt. It was Volhard who had advised him originally to undertake all those years of scientific training, and but for Hitler he would probably have continued in clinical medicine in Germany. But he knew already that he would be welcome and happy in England, and the variety of his earlier scientific experience proved an important element in his later activities here.

During the earlier years of the Second World War, I saw him often at the Royal Society (I was then Biological Secretary). I cannot remember well how it happened—it may have been because of his concern for refugees—but somehow he was adopted by the officers and staff of the Society as a sort of unofficial medical adviser; and as time went on he became the personal friend and physician of many Fellows. At the time of the Tercentenary of the Society in 1960 his name was printed in the programme as "Honorary Physician", in case any of the guests needed help.

In the autumn of 1942 his long ambition to serve his adopted country more directly was satisfied and he was commissioned in the Royal Army Medical Corps. He served as adviser in medicine to the Persia and Iraq force, becoming a lieutenant-colonel, and retired in 1946. A pleasant story is told (by Sir Reader Bullard, in *The Times*) of an American officer in Iran, who had a bad attack of poliomyelitis, from which Rothschild's swift diagnosis and skilled and devoted care (and an iron lung supplied by Lord Nuffield) saved him. Whenever this officer visited England (and Rothschild) later, only a slight limp recalled the danger he had passed through.

From 1946 until his death, Rothschild worked in a large general practice in London. He is remembered by his medical colleagues for the breadth of his knowledge and the wisdom of his advice. And the 'honorary physician' of the Royal Society will be missed by his scientific friends at the functions there to which he regularly, and proudly, went.

His wife, and a son and a daughter, both married, survive him. A. V. HILL

Prof. E. Stiasny

PROF. EDMUND STIASNY, the venerable doyen of leather chemists, died at his home in Helsingborg, Sweden, on October 17 at the age of ninety-three. He was best known to chemists at large for his invention some fifty years ago of the so-called synthetic tannins. These 'syntans' have, structurally, little in common with the natural tannins. However, like these latter, they possess tanning properties, being condensed phenolsulphonic acids.

Stiasny's life-work was dedicated to the introduction of scientific principles into leather manufacture and to the elucidation of the intricate chemical reactions in the tanning process. Together with the late Prof. H. R. Procter, his predecessor as professor of leather chemistry at the University of Leeds, he was a pioneer in the application of science to an ancient art, which was becoming an industry.

Stiasny was born in 1872 in Vienna. He obtained his doctorate at the University of Zürich in 1898. His head professor was Alfred Werner, the originator of co-ordination theory. Stiasny entered on his life's work in 1899 at the Viennese Research Station. At this time little attention was given to the theory of tanning. However, the young scientist could not resist the urge to elucidate the chemistry of these mysterious processes.

His results were very favourably received internationally. Thus, the University of Leeds, seeking a successor to Prof. H. R. Procter, the father of leather chemistry, asked Stiasny to accept this chair. Prof. Stiasny's association with Leeds was of short duration (1909–14), because of the First World War, but it became exceedingly fruitful. While the discovery of the syntans takes the most conspicuous place, the renaissance of teaching and research under Stiasny was perhaps still more important for the Department. He used to dwell on this happy period in his life with pleasure, recalling incidents with his enthusiastic students, the Atkin-Thompson team and Donald Burton, who were to follow him as incumbents of his chair.

He served throughout the First World War as an artillery captain in the Austrian Army. Afterwards he found refuge in Helsingborg, his wife's home town, until, in 1920, he was offered the chair at the Technische Hochschule, Darmstadt. A period of great activity followed (1920–33). An international élite of enthusiastic graduate students flocked about this charming, inspired and inspiring master, who was such a salutary contrast with the formal and stereotyped German professor of those days. Here he endeared himself to his disciples for ever. His studies of protein chemistry problems during the early years were evidently stimulated by Jacques Loeb's *Proteins and the Theory of Colloidal Behavior*. The effect of lyotropic neutral salts on gelatin was investigated using optical rotation measurements, one of the earliest studies using this now-favoured technique. However, his main research concerned the chemistry of basic chromium salts and their tanning potency, resulting in a score of dissertations. By uniting the Ol-structure of basic salts (conceived by Pfeiffer, his life-long friend) and the Bjerrum concept of the protolysis of chromium salts, Stiasny and his school extended our knowledge of these compounds fundamentally. In Stiasny's main work, *Chromgerbung* (1931), the substance of these researches is lucidly presented.

Noticing the *mene tekel* of the approaching deluge, Stiasny resigned from his chair. From 1934 he made his home in Helsingborg. It became a place of pilgrimage for his former students, other friends and colleagues of many lands.

During this period of enforced idleness a welcome interregnum of creative work came with the outbreak of the Second World War. With the supply of tannins becoming critical due to the blockade, the Swedish industry induced Stiasny to develop a domestic syntan manufacture. The research resulted in an industrial production of high-grade syntans. Stiasny's contribution to his adopted country was recognized by the Government with the award of a decoration. By the vicissitudes of fate, the invention of a person exiled by the Nazis came to play an important part in the war effort.

Stiasny was a man of stately exterior, engaging manners and wide culture, and with a warm humanity. As a lecturer and teacher, he was brilliant. His linguistic sense and versatility were exceptional. His writing was lucid, concise and unaffected. The victim of military and political upheavals in the prime of his scientific sphere of activity, with severe personal tribulations as a result, his optimistic way of looking at life, fortified with a dose of stoicism, stood him in good stead. He leaves no near relatives. In the relief of refugee children, he found his last mission in life. K. H. GUSTAVSON

NEWS and VIEWS

Editor of *Nature*: Mr. J. Maddox

JOHN MADDOX, an assistant director of the Nuffield Foundation, has been appointed editor of *Nature* in succession to the late L. J. F. Brimble. It is intended that he shall take up his appointment as soon as he can be released from his present duties as co-ordinator of the Nuffield Science Teaching Project—probably at the end of the present academic year. In the meantime, he will spend some of his spare time helping with the production of *Nature*. Mr. Maddox, who was born in Swansea in 1925, read chemistry at Christ Church, Oxford, before turning to theoretical physics as a research student at King's College, London, under Prof. (then Dr.) C. A. Coulson. In 1949 he was appointed to the University of Manchester as an assistant lecturer and later lecturer in theoretical physics and was chiefly engaged on problems of thermodynamics and statistical mechanics. In 1955, Mr. Maddox joined the *Guardian* (then still the *Manchester Guardian*) as science correspondent, first in Manchester and then London. In that capacity he worked as a reporter of events, a popularizer and as a writer of leaders. Until a few years ago he had been a regular contributor to the *New Scientist*—in fact, he had been associated with that journal since its inception. He worked as science correspondent of the *Washington Post* for several months in 1960, and was chairman of the Association of British Science Writers for two separate terms. In 1962 Mr. Maddox joined the faculty of the Rockefeller Institute, New York, for an academic year. During the past two years he has administered the Nuffield Science Teaching Project—the programme of curriculum develop-

ment begun in 1961 and intended to lead to the design of materials and methods to help with the teaching of science in British schools. Material for use in Ordinary-Level courses for the General Certificate of Education is to be published in May, and the programme as a whole will be completed in 1968.

Prof. J. H. Quastel, F.R.S.: Sixty-fifth Birthday Tribute

THE July 1965 issue of the *Canadian Journal of Biochemistry* consists of scientific papers dedicated as a sixty-fifth birthday tribute to Prof. J. H. Quastel by present and former colleagues in Canada. In brief introductory biographies, Drs. R. M. Johnstone, P. G. Scholefield and K. A. C. Elliott mention some of the major biochemical research fields which have been opened up by Quastel. These include his well-known work at Cambridge on the nature of enzymes and enzyme inhibition, at Cardiff on the biochemistry of the brain and the action of narcotics, at Rothamsted on soil metabolism, soil texture and weed killer, and at Montreal on the biochemistry of cancer, on the action of drugs and on the mechanism of transport across membranes. Sixty-six authors from eight different countries have taken part in this birthday tribute. On retirement from his administrative duties as a professor in the Department of Biochemistry at McGill University, Dr. Quastel will continue his research work as director of the McGill Unit of Cell Metabolism.

Science Administration in the National Institute of General Medical Sciences, National Institutes of Health

Dr. Robert S. Melville and Dr. Carl A. Kuether have been appointed scientist administrators with the Research Grants Branch of the National Institute of General Medical Sciences, National Institutes of Health. The National Institute of General Medical Sciences administers the majority of the basic science research grant projects of the National Institutes of Health. Both Dr. Melville and Dr. Kuether will serve in the Biochemistry Section of the Research Grants Branch, and will be responsible for handling the reviews of applications and the administration of grants for a major segment of the Institute's programme.

Dr. R. S. Melville

Since 1963, Dr. Melville has been chief biochemist and laboratory requirements specialist in the Veterans Administration Central Office. He was previously the chief biochemist in the Veterans Administration Hospital in Iowa City from 1954 until 1963, and a clinical biochemist at St. Luke's Hospital, Chicago, during 1950–54. During the Second World War, Dr. Melville was chief chemist in the Sixth General Hospital Laboratory, United States Army. From 1939 until 1942 he was a research chemist with the Massachusetts General Hospital. Dr. Melville received an A.B. degree from Clark University, Worcester, Massachusetts, in 1937. In 1950 he was awarded a Ph.D. in biochemistry from the State University of Iowa. In July 1965, Dr. Melville was appointed chairman of the Committee on Clinical Chemistry for the Chemistry and Chemistry Technology Division of the National Research Council–National Academy of Sciences. He is a member of the American Association for the Advancement of Science, the American Chemical Society, the Instrument Society of America, Sigma Xi, Phi Lambda Upsilon, Gamma Alpha, a director of the American Board of Clinical Chemists, and a Fellow of the American Association of Clinical Chemists.

Dr. C. A. Kuether

Since 1962, Dr. Kuether has been with the National Science Foundation. Previously, he was associate professor of chemistry at Youngstown University, Ohio, during 1960–62. He has also worked as a senior research biochemist at Eli Lilly and Company, Indianapolis (1951–60), assistant professor of biochemistry at the University of Washington, Seattle (1946–51), instructor and senior instructor in biochemistry at Western Reserve University (1943–46), and teaching Fellow and instructor in biochemistry at the George Washington University (1940–43). Dr. Kuether received an A.B. degree from Miami University, Oxford, Ohio, in 1936, and an M.S. from Wayne State University in 1949. In 1943 he was awarded a Ph.D. in biochemistry from the George Washington University. He is a member of the American Chemical Society, the American Association for the Advancement of Science, the American Institute of Biological Sciences, the Ohio Academy of Science, Phi Eta Sigma, and Sigma Xi, and is a professional lecturer in biochemistry at the George Washington University.

Crop and Animal Husbandry in the Queen's University of Belfast : Prof. J. Morrison, O.B.E.

PROF. JAMES MORRISON retired from the chair of crop and animal husbandry at the Queen's University of Belfast on December 31, 1965, having been specially asked to act until this date to allow for the appointment of his successor, Dr. J. C. Murdoch, by the joint board of the Civil Service and the University. Morrison had a good practical background as an agriculturist, having been directed to work on his home farm in Banffshire during the First World War. Thus he did not graduate, after a brilliant student career at Aberdeen, until 1924. He went to Northern Ireland in 1925 and rose rapidly in the county agricultural service and the Ministry of Agriculture before accepting a transfer in 1933 to the joint appointment in the University and Ministry's Research Division. His keen and practical approach to the teaching of husbandry and his interest in his students were notable from the start. During the Second World War, he was the Ministry's principal officer in charge of the tillage campaign in Northern Ireland, while continuing University work, and in 1947 he toured Poland with the Food and Agriculture Organization mission. Morrison was well known as a leader of agricultural developments, through his numerous extra-mural activities and especially for his work as director of the Agricultural Research Institute at Hillsborough. Here his own special interests have given emphasis to the production, conservation and utilization of grass, illustrating again his practical approach to the special problems of farming in Northern Ireland.

Prof. J. C. Murdoch

DR. J. C. MURDOCH has been appointed to the chair of crop and animal husbandry in Queen's University, Belfast, in succession to Prof. J. Morrison. Dr. Murdoch was born in Ayr. He graduated in agriculture at the University of Glasgow in 1947 and was awarded a Ph.D. in 1950 for work on the growing of sugar beet in Scotland at the University of Edinburgh. Since 1951, as a member of the staff of the National Institute for Research in Dairying, his work has been concerned with the conservation and use of grass products. He has made a special investigation of the factors affecting the losses involved in ensiling grass and their effect on the value of grass silage for milk production. His investigations have ranged from grass quality and field losses through problems of conservation and feeding to the effects of grass products on milk yield and milk quality. His work on silage making has been particularly useful to milk producers in providing evidence on the importance of the basic principles involved in the ensiling process and on the relative insignificance of some of the more glamorous additives which are from time to time recommended for inclusion in silage. His experiments on the factors in silage which affect intake and digestibility and the effect of feed supplements to grass products have found direct application in newer systems of cattle feeding involving *ad libitum* feeding of grass products. Apart from many technical papers on the

production and use of grass products, Dr. Murdoch is the author of a text-book on *Making and Feeding Silage*.

Physical Chemistry at the National Bureau of Standards : Dr. H. White

Dr. Howard White has joined the Institute for Basic Standards of the National Bureau of Standards as assistant chief of the Physical Chemistry Division. In this post, he will direct the work of the Division, particularly as it applies to the physical chemistry of liquids and solutions. Before joining the Bureau, Dr. White was special assistant to the Assistant Secretary of the Navy for Research and Development, where he provided staff functions relating to the provision of funds for, and management of, research in the Navy. From 1959 until 1961, he carried out a research programme in polymers and textiles at Stanford Research Institute. Before this he worked at the Textile Research Institute, where he became director of research and helped to develop and maintain a graduate educational programme in co-operation with Princeton University. Born in Batavia, New York, Dr. White did undergraduate work at Princeton University, where he received an A.B. in 1942. His postgraduate studies took place at the University of Wisconsin, which granted him an M.S. in 1944, and Princeton, where he took his Ph.D. in 1947.

The Royal Society

The report of the Council of the Royal Society for the year ended September 30, 1965, records that progress in planning, etc., concerned with the reconstruction of Nos. 6–9 Carlton House Terrace was slower than expected, and although reconstruction began before September 30, 1965, furnishing and fitting out for occupation will only be completed by July 1967. Besides two additional research professors appointed in November 1964, the first three Leverhulme scholars were also appointed in that month, and in June 1965 the second S. C. Brown Award and Medal was given to Mr. F. T. Bacon for his work on the development of fuel cells. The Royal Society's expedition to the Solomon Islands commenced its field work on July 1, 1965, and a Tristan da Cunha study group was set up to consider the need for continuing facility in the Tristan group of islands to promote biological and geological studies. After examination of a proposal to set up study groups which would enable scientists from a wide range of disciplines to discuss subjects of topical and national interest, a population study group was appointed in April 1965, and an *ad hoc* committee is considering the desirability of establishing a group to deal with long-term questions concerned with water as a resource. The Scientific Research in Schools Committee is at present assisting one hundred and seventeen research projects, and supported, for the second year, a project at the Procter Department of Food and Leather Science, University of Leeds, in which two science masters joined a research team in food science research. The report also summarizes briefly the relations of the Society with the international scientific unions and with antarctic, oceanic, geophysical and space research as well as with the International Biological Programme. Parliamentary grants administered by the Society for 1965–66 totalled £398,000 compared with £251,000 in 1964–65. Research professorships accounted for £82,500, scientific investigations for £113,000, and £124,250 went to international research and scientific congresses, with another £43,000 for the International Biological Programme: £13,450 was spent on scientific publications and £2,500 on libraries assistance.

National Research Council of Canada

The *NRC Review, 1965* (National Research Council of Canada, Ottawa. Pp. 428. NRC No. 8597. Ottawa: National Research Council of Canada, 1965. 2 dollars), provides the usual comprehensive reference work on the activities of the National Research Council of Canada in 1964–65, including those of Canadian Patents and Development, Ltd. Together with the financial report, organization chart and list of members of the Council 1965–66, it includes details of membership of the numerous committees of the Council and a Directory of Staff. There are brief reports from the several divisions on work in progress and to each of these is appended a list of publications during the year. A brief review of the work of the Medical Research Council is also included.

National Museum of Canada : Anthropology Papers

In Anthropology Papers No. 10, Mr. Donald H. Mitchell gives the results of preliminary excavations at a cobble tool site in the Fraser Canyon, British Columbia (National Museum of Canada. Anthropology Papers, No. 10: *Preliminary Excavations at a Cobble Tool Site (DjRi 7) in the Fraser Canyon, British Columbia*, by Donald H. Mitchell. Pp. 20+11 plates. Ottawa: Queen's Printer, 1965). For several years surface finds of early artefacts have been made in this area and the excavations were undertaken to determine if the earlier surface collections with their absence of bi-facially worked artefacts and projectile points were truly representative of the assemblage; to locate artefacts *in situ*; to determine the depth of culture-bearing deposits; and to locate areas of artefact concentration. In general, it was found that the character of the assemblage is essentially the same as depicted by the earlier surface collections: on the first terrace, artefacts and clipping detritus were found to a depth of 44 in. below the surface, and significant clustering of the artefacts is not apparent. The age of the finds is, as yet, uncertain, but according to our present understanding of Fraser Canyon glacial history, the deposits were all river-laid during Post-Pleistocene times.

Salisbury and South Wiltshire Museum

The annual report of the Salisbury and South Wiltshire Museum 1964–65 is a convincing denial of the rumour that the Museum would have to close unless substantially greater funds became available (Pp. 24+4 plates. Salisbury, Wilts.: The Museum, 1965). Now, it is not so much a question of whether it will survive, but in what form it will survive. The report states that steps are actively being taken to increase the revenue from public sources, to increase the membership, and to appeal for capital funds if the first and second aims are successful. Both the County Council and City Council have increased their grants and the local rural district councils have made grants for the first time. Two research projects include the investigation of a possible new alignment for the Roman road Old Sarum to Dorchester and the continuing excavation of the deserted medieval village site of Gomeldon. The amount of voluntary help given to this Museum on the inspiration of the curator continues to be very impressive.

Salamandra

A new journal, *Salamandra*, to deal with the biology of Amphibia and Reptilia, is being published in German (*Salamandra*, Band 1, Helft 1/2; September 1965. Herausgegeben von der Deutschen Gesellschaft für Herpetologie und Terrarienkunde. Pp. 52. Frankfurt/Main-Niederrad: Deutsche Gesellschaft für Herpetologie und Terrarienkunde, 1965). It will be issued quarterly and each article will contain an English summary; all illustrations and photographs will have an English caption. *Salamandra* will also publish reviews of new books and papers on herpetology, including those published in Russia, China, and other Eastern countries. The first issue (September 1965; 1, Parts 1/2) contains an article to celebrate the seventieth birthday of Prof. Robert Mertens. Other articles are by Gerhard Benl,

Pure Chemistry Library

"Neotenie und Albinismus bei *Triturus vulgaris vulgaris*"; Hehuda L. Werner, "Uber die israelischen Geckos der Gattung *Ptyodactylus* und ihre Biologie"; "Leuchtsfflammpen Gro Lux in der Reptilienpflege", by John Merhtens; "Gegen *Strongyloides-Infektionen* bei Reptilien", by Dieter Backhause; and "Zur Biologie der Rassen von *Echis carinatus* (Schneider) 1801", by Othmar Stemmler-Gyger. The journal is mailed only to members of the Society Deutsche Gesellschaft für Herpetologie und Terrarienkunde e V. Membership of the Society is open to all interested individuals, other societies and institutions. Annual subscriptions are DM 12 (plus DM 2 for entrance fees) within Europe, and 4 dollars (plus 0·5 dollar for entrance fee) abroad. Further information can be obtained from Dr. D. Backhaus, 6 Frankfurt/Main-Niederrad, Gerauer Strade 69b, or from Alfred A. Schmidt, 6 Bergen-Enkeim bei Frankfurt/Main, Muhibachstrade 5.

Freshwater Habitats of *Culex pipiens fatigans* in Rangoon

C. H. Fernando, of the Department of Zoology, University of Singapore, investigated twenty-one freshwater habitats in Rangoon during February 1963 in relation to the ecology of *Culex pipiens fatigans* (Wiedemann) (*Ceylon Journal of Medical Science*, 13; December 1964). Ten habitats were positive and eleven negative at the time of the investigation. They represent a fair range of freshwater habitats in Rangoon and show a range of pollution conditions. The fauna and flora show an overall reduction with increase of pollution and, among the fauna, a high proportion of 'pan South-East Asian' species occur in polluted habitats. The bacterial flora was studied very cursorily and needs more detailed investigation. In *C. fatigans* the tolerance for most natural organic and inorganic materials is high, though physical factors may influence densities. Oviposition sites may be of considerable importance for high densities of *C. fatigans*. High densities of this insect are associated with decaying organic matter, unsuitability for other fauna and flora in general and the accompanying reduction of predatory animals, especially insects. The Notonectidae are perhaps the most important predators of *C. fatigans* and these penetrate into polluted waters also. In the most heavily polluted habitats, *Armigeres* might well prove a competitor and even a predator of *C. fatigans*.

Microwaves in Action

Many phenomena affecting our everyday life are manifest in the form of radiant energy or electromagnetic waves. These vary greatly in length and in frequency of vibration; the longest are more than 6,000 miles from crest to crest with vibration only 30 times per sec; at the other extreme are cosmic rays as short as $1{\cdot}5 \times 10^{-9}$ in., with vibrations more than 30×10^{21} times per sec. An informative chart in colour and entitled "The Radiant Energy Spectrum", covering the full range of wavelengths and frequencies, is featured in *Vectors*, a quarterly publication of the Hughes Aircraft Company of California (7, No. 3; third quarter, 1965. Hughes Aircraft Co., Culver City, California). Selected in this issue for special discussion are the micro-waves, and in an account of their uses and potentialities, in an article entitled "Microwaves in Action", some interesting details of their place in the radiant energy spectrum and in industry are given. The microwave region is now generally considered to span waves from about 30 cm down to about 0·1 mm in length, with frequencies between 1,000 and 5×10^6 megacycles; the part below 1 cm wave-length is known as the millimetre-wave region.

Among some of the valuable properties of microwaves are that they can penetrate fog or haze; this form of radiation can be sent out and controlled like a searchlight beam, and if part of that beam strikes an object, it is reflected back; this is the basis of the ranging and detecting devices called 'radar'. Microwaves are well adapted for communications work; they can be transmitted in a line-of-sight pencil beam from one place to another, and in this application they permit many simultaneous channels of communication. A more recent application of microwaves—one destined to grow in importance—is for cooking foods; here the waves penetrate the food, which absorbs them in the form of heat. They are used not only for roasting, but for drying, defrosting and frying. In industry, microwaves find many outlets, such as control of materials, including moisture content; in printing they are used for drying inks in colour lithography, reducing delays of hours to a matter of minutes. Diathermy has long been used for the relief of pain by dielectric heating of body tissue, frequencies for this purpose being about 10 Mc/s; it has been found, however, that microwaves of 2,400 to 2,500 Mc/s may be more efficient because they can be directed to specific areas of the body without contact. It is predicted that microwaves have a brilliant future; microwave receivers in homes and schools receiving television direct from *Early Bird* satellites is one of the most exciting possibilities suggested.

Concrete Staved Silos for storing High-moisture Barley

Among its many and varied activities, the Agricultural Research Council sponsors an Experimental Farm Buildings Scheme which provides for co-operation with farmers in investigations of experimental farm buildings and of experimental ideas affecting buildings. Grants are made towards the capital cost of these buildings and in return farmers provide data for a limited period about the buildings and generally about the operations conducted therein. The practical application of this scheme is well illustrated by the publication of a recent report entitled: "The Use of Concrete Staved Silos for Storing High-Moisture Barley" (*Experimental Farm Buildings—Report No. 4*. By H. J. M. Messer, J. M. Hill, Dr. R. Whittenbury and Dr. J. Lacey. Pp. 24. London: Agricultural Research Council. Obtainable from H.M.S.O., 1965. 3*s*. 6*d*. net). This report is in three parts; (*a*) effect on grain temperature, nutrient content, *p*H value and the composition of the intergranular air, by H. J. M. Messer; (*b*) microbiological changes in ensiled grain, by R. Whittenbury; and (*c*) interim report on the micro flora of airborne dust from moist-stored barley grain, by J. Lacey. In summary, seven concrete staved silos designed for unloading from the top were filled with damp barley from the 1964 harvest. Records of harvesting, filling, unloading and rolling the barley were kept throughout the experiment; changes in the stored grain and in the atmosphere in the silos were determined. It was found that conditions in the silos were sufficiently anaerobic to prevent serious deterioration of the grain so long as it was removed to a greater depth than 3 in. each day. No difficulties were experienced with unloading from the top. Trials of feeding and digestibility with dairy cows indicated that there was no significant nutritional difference between this barley and conventionally dried barley. From the biological point of view, it was found that yeasts and lactic acid bacteria were the dominant micro-organisms in anaerobically stored barley carrying 18–40 per cent moisture. Potentially pathogenic fungi and actinomycetes were found in all silos, but their numbers were minimized by efficient top sealing and by using the barley at a sufficiently fast rate to avoid self-heating. A precautionary measure is noted: efficient dust respirators should be worn when entering silos containing high-moisture grain.

Royal Society of South Africa

The following have been elected Fellows of the Royal Society of South Africa: Dr. L. H. Ahrens, Dr. D. H. Davies, Dr. V. Fitzsimons, Dr. E. S. W. Simpson and Dr. E. M. van Zinderen Bakker.

Fisheries Division of the Food and Agriculture Organization of the United Nations

On January 1 the Fisheries Division of the Food and Agriculture Organization of the United Nations became a department, consisting of two divisions, a Fishery Resources and Exploitation Division, the acting director of which is Mr. S. J. Holt, and a Fishery Economics and Products Division, the acting director of which is Mr. R. W. Harrison. Mr. R. I. Jackson, director of the former Fisheries Division, has been appointed assistant director-general, and Mr. F. E. Popper has been appointed director of programme co-ordination and operations for the new department, and will act as deputy to Mr. Jackson.

Academy of Sciences of the Socialist Republic of Romania

The following have been elected honorary members of the Academy of Sciences of the Socialist Republic of Romania: Prof. J. D. Bernal (professor of crystallography at Birkbeck College, London); Prof. A. V. Hill (emeritus professor of physiology in the University of London); Sir Robert Robinson (emeritus professor of chemistry in the University of Oxford); Dr. G. Constantinescu. Sir Rudolph Peters (professor emeritus of biochemistry at the University of Oxford) has been elected a corresponding member of the Academy.

Institution of Mechanical Engineers : James Clayton Fellowship

A James Clayton Fellowship, tenable for 2 years, to enable an engineer to work in collaboration with surgeons and doctors on a suitable project, is to be awarded by the Institution of Mechanical Engineers on the recommendation of its working party on medical engineering. The sum granted will be adequate to cover living expenses during the tenure of the award and the value of the Fellowship will be assessed accordingly. Applications, on forms available from the Institution, 1 Birdcage Walk, London, S.W.1, are required not later than April 13, 1966, from candidates, who must be more than 23 and have obtained an engineering degree or have satisfied the Institution's examination requirements for graduate membership by some other means. They should preferably have had not less than 18 months' practical experience in industry. Normally, applicants for the James Clayton Fellowship must present a planned project for approval, but in this case a successful applicant who has a strong inclination towards medical work but no direct contacts in that field will be helped to find a suitable project.

A. A. Benedetti-Pichler Memorial Award in Microchemical Techniques

The American Microchemical Society has created a fund to commemorate the work of the late Dr. A. A. Benedetti-Pichler. The award will be made to an individual who has made outstanding contributions to the practice or teaching of micro-techniques. The award will be given at regular intervals with the understanding that the recipient will give a lecture at a gathering of analytical chemists covering the field for which the award has been designed. Nominations are now being sought and must be in the hands of the committee by April 1, 1966. A letter of 300 words or less, giving the name and address of the nominee and citing, in general, his work, should be sent to the chairman of the 1966 committee, Mr. David B. Sabine, U.S. Vitamin and Pharmaceutical Corporation, Yonkers, New York. The Fund is not closed, and gifts payable to the A. A. Benedetti-Pichler Memorial Fund may be sent to the chairman.

University News:

Belfast

Dr. F. A. Vick, former director of the Atomic Energy Research Establishment, Harwell, has been appointed vice-chancellor.

Birmingham

Dr. T. S. M. Maclean has been appointed senior lecturer in the Department of Electronic and Electrical Engineering. The following Research Fellows have also been appointed: Dr. S. M. Amir and P. J. Somers (chemistry); Dr. I. E. Harris (physical metallurgy). The title of reader has been conferred on the following: Dr. J. S. Hough (applied biochemistry and brewing science); Dr. D. G. Walker (biochemistry); Dr. J. H. Edwards (human genetics).

London

The title of professor of geology has been conferred on Dr. J. G. Ramsay in respect of his post at the Imperial College of Science and Technology. The title of reader in geography has been conferred on Dr. J. H. G. Lebon in respect of his post at the School of Oriental and African Studies.

Announcements

The following have been elected honorary members of the Genetical Society: Prof. N. P. Dubinin, Dr. M. Demerec and Prof. C. D. Darlington.

Dr. B. Benjamin has been elected president of the Institute of Actuaries in succession to Sir Herbert Tetley, whose term of office will expire on June 13.

Dr. W. Tuve has been appointed chief of the Research Training Grants Branch, National Institute of General Medical Sciences, National Institutes of Health, Bethesda, Maryland.

The fourteenth annual general meeting of the Society for Water Treatment and Examination will be held in London on March 11. Further information can be obtained from the Secretary, Society for Water Treatment and Examination, 41 Carshalton Road, Sutton, Surrey.

An exhibit featuring the meteorite which fell at Barwell, Leicestershire, on December 24, 1965, is now mounted at the Geological Museum, London. The exhibit includes fragments of the meteorite, an account of its fall and photographs and maps of the locations where fragments have been found.

A symposium on "Non-linear Optics", organized by the National Academy of Sciences of India, will be held at Agra during February 26–28. Further information can be obtained from Prof. Vachaspati, Department of Physics, University of Allahabad, Allahabad.

A conference on "Stresses in Structures and Machinery", arranged under the auspices of the Institution of Civil Engineers, will be held at the Institution during March 3–5. Further information can be obtained from the Institution of Civil Engineers, Great George Street, London, S.W.1.

The twentieth annual symposium on fundamental cancer research entitled "Carcinogenesis: A Broad Critique", arranged by the University of Texas M. D. Anderson Hospital and Tumor Institute, will be held in Houston during March 7–9. Further information can be obtained from the Symposium Committee, University of Texas M. D. Anderson Hospital and Tumor Institute, Texas Medical Center, Houston, Texas.

A celebration to mark the centenary of the birth of Sir Arthur Keith (1866–1955), conservator of the Hunterian Museum and master of the Buckston Browne Farm, will be held at the Royal College of Surgeons of England on February 14. An introductory address will be given by Lord Brock and short papers delivered on aspects of Sir Arthur's work at the Royal College of Surgeons. The Sir Arthur Keith Memorial Lecture will be delivered by Sir Wilfrid Le Gros Clark. Further information can be obtained from the Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2.

UNITED KINGDOM ATOMIC ENERGY AUTHORITY

THE eleventh annual report of the Atomic Energy Authority covers the year ended March 31, 1965*. During this period the Authority's staff continued to decrease, but only by about 3 per cent compared with 5 per cent in the previous year, the reduction in the civil research and development programmes being very slight. By March 31, 1965, nuclear reactors in the United Kingdom had fed some 2,600 million units of electricity to the grid, substantially more than the total for the whole of the West outside Britain, and shortly before the end of the year the prototype advanced gas-cooled reactor at Windscale completed two years' operation, in which it had produced more than 350 million units of electricity for the grid and demonstrated a plant availability of 85 per cent. It is already clear from tenders for the Dungeness *B* station of the Central Electricity Generating Board that, whichever reactor station is chosen, nuclear power will be fully competitive from the beginning of the second nuclear power programme.

In 1964–65 expenditure from parliamentary grants on the Authority's programme of civil research and development was £47·5 million, of which £37·5 million was current expenditure and £10 million was for capital facilities. Some 2,840 graduate or professional engineers and scientists were employed on the programme on March 31, 1965, of whom 160 were working on projects for other organizations; 360 were employed on basic research, for which expenditure at present is estimated at £5 million and capital expenditure at £1·5 million; 80 on isotope research, for which expenditure at present is estimated at £500,000; 120 on basic research into health and safety, for which the expenditure at present is £1 million; and 200 on plasma physics and fusion research, for which expenditure at present is £3·5 million and capital expenditure is £1·5 million. In the reactor research and development programme 500 were employed in work on gas-cooled systems (current expenditure £9 million, capital £1 million); 480 in work on water-moderated systems (£5·5 million and £4 million, respectively); 575 on fast systems (£9 million and £1·5 million, respectively); and 365 on general reactor technology (£4 million and £500,000, respectively). The report refers to the new requirement under the Science and Technology Act, 1965, for the Authority to undertake research and development in science and technology outside the nuclear energy field, and the first major application is expected to be a programme of development of desalination techniques.

Research on reactor systems includes a continuing programme of nuclear measurements to provide data for calculating the physical characteristics of proposed reactors, and equipment has been installed which stores and processes the experimental information obtained from a modern high-intensity machine, and at the same time allows the experimenter to inspect the results as they come in, by displaying them on a cathode ray oscilloscope. The installation is probably the first of its kind in Europe. General investigations of the physics of reactor systems have included measurements in thermal systems of neutron energy spectra to discover whether the processes of energy transfer between neutrons and moderator atoms are correctly described by proposed scattering laws. The novel reactor types and applications being investigated include the fused salt reactors, which show long-term promise. Progress has been made in the field of control science, with the ultimate aim of achieving computer control of nuclear power plants, the main areas of progress being in optimal theory, studies of experimental dynamics and analytical techniques. Investigations into the behaviour of ceramic fuels at high burn-up included investigations of uranium dioxide and the mixed oxides of uranium and plutonium. Research on canning and structural materials has been concerned with the effects of irradiation, with corrosion and with methods of fabrication. To improve understanding of the effects of irradiating graphite, further work has been carried out on the formation and growth of defects in this material, and the investigation of the reaction between irradiated carbon dioxide and graphite has been continued. Research on heat transfer is now concentrated on problems connected with water and steam coolants.

General research has covered work on materials and their properties, and the effect of irradiation on them; on processes, metallurgical and chemical; nuclear and theoretical physics; instruments and techniques and the direct conversion of heat to electricity; and stress is laid on close collaboration with the university research departments, as well as with industry and overseas agencies. Experiments on the chemical effects of irradiation have been supported by researches into the basic principles underlining these effects. That on ceramic fuels is supported by research into the basic properties of ceramic materials generally. Work on the physical properties of plutonium has included measurements in the alpha phase and on stabilized alloys of some of the other phases. The reasons for the brittle nature of beryllium are now beginning to be understood and research has continued on fluidization, the process in which solids are made to behave to some extent like liquids by blowing gas through a bed of fine particles, and it is now possible to predict, on a logical basis, the behaviour of a fluidized bed in which a chemical reaction is occurring, at least in simple systems.

Research in experimental nuclear physics is directed to the elucidation of nuclear structure and of the basic nuclear interaction forces, while a major effort at Harwell is devoted to studying solid-state physics and the theory of radiation damage. Research on solid-state particle detectors has also continued, while the exploratory programme at Harwell on methods for directly converting heat to electrical energy has continued, with further examinations of the feasibility of the magneto-hydrodynamic method using non-equilibrium ionization of the hot gas. Research on non-fissile ceramics appears likely to have applications in other industries, and the production of high-density, fine-grained alumina bodies has been investigated. Attention is being paid to developing fibre structures by normal processes of fabrication and heat treatment, and, in an aluminium-based material, strength at high temperatures was comparable with or better than that of other high-strength materials such as sintered aluminium powder. Research on organic high polymers has been directed towards improving properties, and a fire-retardant, polyurethane foam, has been developed which also has higher compressive strength and will work at higher temperatures than is possible with other materials at present available. In a programme of work on non-destructive testing, a method has been perfected for obtaining a detailed survey of the distribution of fuel in a plate-type fuel element.

In fusion research, the theoretical and experimental development of magnetic wells has been a main feature of the work during the past year. Two sets of experiments have been used to examine the behaviour of low-density plasma in open-ended magnetic traps, and two other experimental groups are studying hot dense plasma in open-ended magnetic traps. Fundamental investigations of specific aspects of plasma behaviour have continued

* United Kingdom Atomic Energy Authority. Eleventh Annual Report for the period 1st April, 1964–31st March, 1965. Pp. x+102+8 photographs. (London: H.M.S O , 1965.) 8s. net.

in carefully controlled environments, free from many of the complexities which would accompany them in containment experiments. Solid dielectric switches have been developed, which have proved to be capable of consistent operation under the onerous conditions needed for controlling high-energy discharges. Research concerned with health and safety has included the development and testing of a 'cascade centripeter' for the determination of aerosol activities as a function of particle size, and a series of reports is being issued on the marine radiobiological investigations at Chapel Cross. Good progress was made in safety studies of the steam-generating heavy-water reactor, and an experimental programme to provide data checks for calculations of mixed plutonium and uranium systems has been initiated in which results of theoretical calculations agreed closely with experimental data. A team has been set up at Harwell to conduct inhalation investigations on human volunteers using radioactive vapours and labelled aerosols. Some account is given in the report of the Authority's relations with industry and with the universities. Extra-mural agreements between the Authority and universities and colleges already involve some 250 research workers and there is frequent interchange of staff between the Authority and universities, home and overseas, in the course of normal appointments as well as by exchange and attachment. During the long vacations in any year there are usually some 400 university students, research workers and staff working in or in close contact with Authority establishments.

Major changes in the programme of the Postgraduate Education Centre, Harwell, included the ending of the 14-week courses on radiation potential and the 20-week standard courses on radiation technology. A total of 858 students attended the 30 full-time courses, of whom 782 were British, 448 being from Authority staff. The 16 part-time courses were attended by about 1,100 students, mainly from the Atomic Energy Research Establishments. An innovation was a 4-day introduction to technology for 25 pupils from the sixth forms of grammar schools. By the end of 1964, 3,638 students had attended 165 courses at the Isotope School, the 15 courses held during the year having an attendance of 307. Seven 3-week courses at the Calder Operation School on the operation of magnox reactors were attended by 58 British and 9 overseas students and the four 2-week courses for Authority staff were attended by 32 staff.

An illustrated summary of the eleventh annual report has also been issued by the Authority, and this also includes a summary of the Central Electricity Generating Board's assessment of the Advanced Gas-cooled Reactor.

UNIVERSITY FINANCE IN BRITAIN

AS with the previous *Returns from Universities and University Colleges in receipt of Exchequer Grant**, those for the academic year 1963–64 are not accompanied by a general survey of activities, which is now issued as a separate publication. The grant list for 1963–64 covered 30 universities and 2 colleges, 25 of the former being in England, 1 in Wales and 4 in Scotland. Of the 2 colleges, the Royal College of Science and Technology, Glasgow, was granted a Charter as the University of Strathclyde in August 1964. The Universities of Kent and Lancaster received grants for the first time.

The number of full-time students in British universities increased to 126,445, compared with 119,004 in 1962–63, and of these 99,469 were reading for a first degree, 3,390 for a first diploma, 22,555 were engaged on research or other advanced work, and 1,031 were attending courses not leading to a degree or diploma. Of the full-time students, 73·3 per cent were men and 26·7 per cent were women, the small but steady annual increase in the proportion of women since 1959–60 continuing. 18,133 were in the Universities of Oxford and Cambridge, 23,955 in the University of London, 53,989 in other English universities and colleges, 8,447 in the University of Wales, and 21,921 in the Scottish universities. There were 13,786 students from overseas, 7,271 being postgraduate, of whom 7,562 were from within the Commonwealth; the percentage of overseas students was 10·9 compared with a peak of 11·5 per cent in 1961–62. Of the full-time students, 31·1 per cent were in colleges or halls of residence, 50·4 per cent in lodgings and 18·5 per cent at home, compared with 28·1, 40·9 and 31·0, respectively, in 1953–54. The proportions continue to vary widely for men and women, and in different universities: in Scotland only 11·7 per cent of men and 20·8 per cent of women are in colleges or halls of residence, while 45·2 per cent of men and 41·6 per cent of women are at home; for the Universities of Oxford and Cambridge the corresponding percentages are 56·0 and 74·4 and 2·0 and 3·0, respectively.

Of the 92,636 full-time men students, 23·4 per cent were in arts, 12·5 per cent in social studies, 28·3 per cent in science, 19·5 per cent in applied science, and 10·6 per cent in medicine; for the 33,809 women students the corresponding figures are 51·4, 11·6, 24·0, 1·2 and 9·0. Of the 22,555 postgraduate students, 3,801 were taking postgraduate courses in teacher training; 4,001 of the remainder were in arts, 2,493 in social studies, 6,882 in science, 3,551 in applied science, 1,300 in medicine, and 364 in agriculture. Of the 34,773 full-time students entered for the first time in 1963–64, 33,147 were reading for a first degree and 1,626 for a first diploma; 10,107 were women; 11,016 were in arts, 4,773 in social studies, 9,458 in science, 5,249 in applied science, and 2,770 in medicine. The figures for science and applied science compare with 9,224 and 4,965 in 1962–63, and over the past decade the intake in science has climbed steeply, whereas that in medicine has only increased slightly, and that in agriculture and forestry and veterinary science has remained relatively static.

The proportion of State-assisted students again increased, from 88·4 per cent in 1962–63 to 89·9 per cent in 1963–64, compared with 71·9 per cent in 1953–54, ranging from 94·5 per cent in Wales, 93·4 per cent at English universities other than London, Oxford or Cambridge, 91·4 per cent at Oxford and 85·7 per cent in Scotland to 83·5 per cent for the University of London. There were 16,528 part-time students (4,555 from overseas) and, of these, 13,116 were in English and 3,205 in Scottish universities. Almost half the part-time students were in six institutions of the University of London; 6,814 were postgraduate, 2,379 being in arts, 838 in science, 333 in applied science, 2,431 in medicine, and 629 in social studies. Of the 25,954 first degrees obtained, 18,186 were honours; and of the total 30·5 per cent were in science, 13·3 per cent in applied science, 6·9 per cent in medicine, and 13·3 per cent in social studies. Full-time teaching and research staff, excluding Oxford and Cambridge, increased to 14,939 (13,801 in 1962–63), and 27·8 per cent are now in science, 14·3 per cent in applied science, 15·8 per cent in medicine and 9·3 per cent in social studies: 11·6 per cent were professors, 6·5 per cent readers, 12·7 per cent senior lecturers and 46 per cent lecturers. Including Oxford and Cambridge, the full-time academic staff totalled 15,252, of whom 4,250 were in science, 2,156 in applied science, and 2,397 in medicine.

* University Grants Committee. *Returns from Universities and University Colleges in receipt of Exchequer Grant, Academic Year 1963–1964*. Pp. v+46. (London: H.M.S.O., 1965.) (Cmnd. 2778) 6*s*. 6*d*. net.

Of the recurrent income of £104,441,063 (£86,402,542 in 1962–63), £74,500,135 was from Treasury grants (70·5 per cent) and £888,277 from grants from Government departments; £9,156,682 (8·8 per cent) from fees; £2,188,214 (2·1 per cent) from endowments; £1,734,077 (1·7 per cent) from local authority grants; £520,699 from donations and subscriptions; and £12,043,222 (11·5 per cent) from payments for research. For English, Welsh and Scottish institutions the respective total incomes were: £83,656,716, £5,668,742, and £15,115,605. Non-recurrent Treasury grants totalled £43,295,545 (£36,481,424 in 1962–63), and of this £26,869,345 was in respect of building work, £4,133,745 professional fees, £10,334,363 furniture and equipment, and £1,958,092 purchases of sites and property. Since 1952, grants for furniture and equipment have been confined to new accommodation, including buildings adapted for new purposes. Of the recurrent expenditure of £102,301,794, 6·7 per cent was on administration, 43·4 per cent on salaries and superannuation of teaching staff, 12·1 per cent on departmental wages (technicians and laboratory assistants), 16·6 per cent on departmental and laboratory maintenance, 2·9 per cent on repairs and maintenance of buildings, and 11·1 per cent on rates, insurance, heat, light, water, etc. Of the expenditure of £3,946,646 on libraries, £2,093,719 was on salaries and wages, etc., of staff, and only £957,017 on books and £461,855 on periodicals; only London (£155,596), Oxford (£106,421), Cambridge (£71,074) and Leeds (£61,840) spent more than £50,000 on books, and only London (£115,663), Cambridge (£35,407), Oxford (£34,570), Edinburgh (£23,291) and Glasgow (£20,553) more than £20,000 on periodicals.

EMPLOYMENT OF GRADUATES IN BIOLOGICAL SUBJECTS 1962/63

WHILE covering much of the ground dealt with in its first report, the recently published second annual report (1962–63) of the University Grants Committee on the first employment of university graduates* includes an analysis of the employment of men and women who have graduated with Masters' or Doctors' degrees by thesis and/or examination (Table 1).

Table 1. Employment of Graduates in Biological Subjects (1962–63)

Degree subjects	Total graduating	Research training	Teacher training	Available for employment	Gained employment home and abroad	Seeking posts 31.12.63
Biochemistry	195 (163)	98 (80)	6 (6)	81 (68)	76 (58)	4 (4)
Botany	258 (289)	93 (111)	66 (55)	89 (112)	77 (91)	7 (12)
Pharmacy/pharmacology	278 (250)	54 (36)	0 (0)	209 (209)	203 (199)	1 (2)
Physiology and/or anatomy	386 (336)	76 (52)	6 (4)	33 (25)	30 (15)	1 (3)
Zoology	375 (335)	124 (110)	66 (82)	170 (120)	138 (97)	18 (15)
General biology	248 (264)	19 (31)	74 (70)	128 (125)	103 (101)	12 (11)
Agriculture	345 (393)	98 (105)	11 (10)	192 (122)	163 (193)	19 (27)
Totals	2,085(2,030)	562 (525)	229 (227)	902 (892)	792 (754)	62 (74)

Table 1, abstracted by A. C. Simpson from the two reports (the 1961–62 figures being given in brackets), shows surprising differences between the various sections of biology when the figures for the two years are compared. Thus, while the numbers graduating in zoology and biochemistry increased 12 per cent and 20 per cent, respectively, the numbers graduating in botany and agriculture decreased by 10 per cent and 12 per cent. However, the number of zoology graduates going on to teacher training fell by 20 per cent while the number of botanists increased by 20 per cent. To the numbers of graduates that were still seeking employment 6 months after graduating, the figure for all biologists covered by Table 1 for 1962/3 was 3·0 per cent of those graduating compared with 2·5 per cent for chemists and 1 8 per cent for physicists. The figure is not so satisfactory when those continuing study are excluded and the numbers available for employment in the various sections of biology are considered separately; for botany, zoology and general biology respectively, the percentages of those available for employment who were still seeking employment were 8 per cent, 11 per cent and 9 per cent, respectively. On the other hand, only two of the 434 biologists graduating with higher degrees failed to get employment within six months of graduation.

Table 2 gives an analysis of the employment categories of men and women who qualified for first and higher degrees in biochemistry, botany and zoology in 1962/63 and obtained employment in Britain.

Table 2. Graduates in Biochemistry, Botany and Zoology who obtained Employment in Britain (1962–63)

Degree:	Biochemistry First	Biochemistry Higher	Botany First	Botany Higher	Zoology First	Zoology Higher	Totals First	Totals Higher
Civil service	5	2	3	8	14	5	22	15
Local government	17	—	5	1	20	2	42	3
Universities and technical colleges	23	26	22	28	26	33	71	87
Schools (excluding those having taken teacher training)	7	—	26	9	37	4	70	13
Industry and commerce	13	8	14	5	13	2	40	15
Others	8	4	6	1	18	3	32	8
	73	40	76	52	128	49	277	141

It is seen that more than half those employed who obtained higher degrees in biochemistry, botany or zoology found their first employment within the universities and technical colleges, that schools took on 70 graduates immediately after their first degrees, apart from the 138 who went into teacher training courses with biochemistry, botany and zoology degrees, and that industry and commerce took nearly three times as many graduates straight from their first degrees than straight after taking higher degrees.

* *J. Inst Biol.*, 18, No. 3 (1965).

SCIENTIFIC POLICY IN BELGIUM

THE fifth annual report of the National Council for Scientific Policy, Belgium, covers the activities of the Council during 1964*. Its seven chapters review in succession the development of scientific policy at the national and international level; the budget for science; the organization of research; the expansion of higher education; the scientific establishments of the State; the distribution of scientific manpower; and the level of scientific potential in 1961. Reports or recommendations were presented to the Government on the expansion or adaptation of higher education at university level; the State scientific establishments and services; the development and finance of nuclear research; the status of the teaching hospitals; and the budget for science for 1965. At the international level, besides investigating the structure of scientific policy, the Council was concerned with the support of Euratom and the European Space Research Organization. The budget for science has

* Conseil National de la Politique Scientifique. *Rapport Annuel, 1964*. Pp. 200. (Bruxelles: Conseil National de la Politique Scientifique, 1965.)

grown from 2,622 million francs in 1960 to 4,690 million francs in 1964, 85 per cent of which is for the Departments of Education (58 per cent) and Economic Affairs (27 per cent), and, of this, 24·5 per cent and 26·5 per cent, respectively, are for research. Universities and institutions of higher education received 2,714 million francs; Government scientific establishments, 1,472 million francs; while 298 million francs went to the private sector.

Expenditure on fundamental research is estimated at 1,500 million francs and on applied research at 1,446 million francs. The Council recommends an annual growth of 15 per cent in the scientific budget as essential to provide normal development of higher education and research; grants for particular fields of science should be weighted within this limit.

The distribution of the scientific budget between different fields of science and institutions is analysed in some detail in the following chapter, which also discusses the reorganization of nuclear research and space research. The Government has accepted the Council's recommendation for the establishment of new university institutions at Anvers and Mons. The Council, after examining the work of the teaching hospitals, has recommended drawing a distinction between them and certain specialized and other university services and is now considering a general programme of development for the biological and medical services, having regard to the legal and social as well as the financial aspects. Some integration and regrouping of some of the scientific services and establishments of the State is also recommended and there is also a brief discussion of the status and organization of scientific staff in the Government service and in the State universities.

The 2,059 professionally qualified scientific staff, the 2,334 possessing technical diplomas and the 7,470 technicians and others engaged in scientific activities in 1961 were employed in 1,377 institutions. Of these latter, 180 were concerned with chemistry, rubber or pharmacy, 58 with metallurgy, 435 with metal manufacture, and 176 with textiles; the corresponding figures for qualified scientific staff are 874, 203, 450, and 73, respectively; for technical staff, 791, 219, 755 and 122; and for technicians, etc., 2,932, 1,000, 2,359, and 238. The corresponding distribution of the total expenditure of 2,882 million francs was 1,282 million francs, 235·5 million francs, 1,029 million francs, and 47 million francs, respectively. There is also a brief account of the activities of the National Foundation for the Finance of Scientific Research.

ASSESSMENT PROCEDURES IN SECONDARY SCHOOL SCIENCE

J. F. EGGLESTON holds a research fellowship in the School of Education, University of Leicester, where special thought is being given to the teaching of science in schools along with related questions of syllabuses and examinations. His paper* is mainly concerned with the examinations for the Certificate of Secondary Education, which in the past few years have been taken by an increasing number of boys and girls of Newsom quality, that is, those not normally expected to become sixth-form specialists. His essay merits attention, for it amounts to an interim report on a problem which is entering on a period of rapid change, while with varying impact all examinations in science are subject to the same considerations.

As Eggleston points out, in the past, examinations have served a dual purpose, providing measurements of achievement and predictions for the future. Up to now the first of these aims has been predominant, with its emphasis on the factual content of the syllabus to the detriment of original enquiry and practical experience. In support of this contention he draws on a survey of examinations at 'O' level, by R. W. Crossland and R. Amos, recently published in *Biology and Human Affairs*†.

The Boards which have been established to conduct examinations for the Certificate of Secondary Education have attempted to devise courses of work and tests to meet a wider range of requirements, as, for example, to make observations, develop manipulative skill, foster the ability to solve problems, and develop the pupils' ability to 'think scientifically'. Following R. L. Ebel and B. S. Bloom in America, and J. Furst in England, Eggleston maintains that aims like these are much too general; to increase their validity they need to be defined in more precise terms. He also thinks that no count should be taken of pupils' interests and enthusiasms, partly because as attributes they are subjective, and also because in many cases they are ephemeral.

He does not deal with oral examinations, which raise problems of a different kind. As for practical tests, he holds that under favourable conditions they measure qualities not disclosed by other procedures. Biology teachers appear to be most convinced of their validity, at the level of the Certificate of Secondary Education, although, owing to difficulties in arranging for them, some Boards do not make use of them at all. Similarly, a good case can be made for supplementary assessments based on course work, made by teachers who are in constant touch with their pupils, but again, subjective elements are involved. Altogether, in reading this essay, one is impressed by the number of questions which remain wide open, and by the spirit of amateurism which still prevails in a situation which urgently calls for hard scientific experiment and thought.

Even when some of these questions come nearer to solution, others of comparable import will remain. One, for example, is the advisability of holding any examinations at all at Certificate of Secondary Education level since they draw a line between the pupils who pass and the large number of children who fail to make the grade. Still, since this system is now in being it may call for modification rather than immediate abolition. Another question is the narrowing of interest and reduction in the teacher's initiative brought about by any examination syllabus; while a third, of similar classroom applicability, is that of the sophistication introduced by teachers who seek to anticipate examiners' requirements, as in question-spotting. This consideration produces more distortion in the simpler kinds of tests.

Beyond the schoolroom other questions await attention. For example, scientific ability is protean in its diversity; it cannot be reduced to a tidy single entity; and most of the outstanding discoveries in science cut across current techniques and systems of reasoning, they cannot be prepared for by training in making observations, and the spirit of enquiry is not a kind of searchlight which can be switched on and off at will. Scientists need time to brood, and their single-mindedness is something of spontaneous growth. How is it to be fostered? How is it to be assessed?

Then, no course in science can claim to be truly educational unless thought is given to its informational content, including appreciation of some of the major applications which provide the material fabric of our civilization; and at a higher level, all young people should be given some

* *A Critical Review of Assessment Procedures in Secondary School Science (with Special Reference to C.S.E.).* By J. F. Eggleston. Pp. 56. (School of Education, University of Leicester, 1965.) 5*s*.

† Crossland, R. W., and Amos, R., *Biol and Hum. Affairs*, **30**, 35 (1965).

understanding of the part science plays in cultural life, including moral and even, perhaps, spiritual issues. In this sense the ideological content of syllabuses will have to be brought under review. Points like these pose difficult questions for teachers and examiners, but if in their training young scientists are to be treated wholly as specialists they will remain nothing but specialists when they grow up. R. Weatherall

REPORT OF THE AGRICULTURAL RESEARCH COUNCIL 1963–65

THE Report of the Agricultural Research Council for the years 1963–65 (Cmnd. 2792, H.M. Stationery Office, 8*s*.) describes the work of twelve out of the forty-seven institutes and units for which the council is, in effect, responsible; summarizes some of the major developments in the two years under review; and, in so doing, demonstrates the wide range of modern agricultural research. Thus, in soils, work (some of which may be relevant to public health) on the persistence of organo-chlorine insecticides shows that a single dressing of dieldrin has effectively controlled carrot fly, *Psila rosae*, for nine years, while very low residues of this compound reduced the natural enemies of the cabbage root fly, *Erioischia brassicae*, and thus aided the survival of this pest. If the placement of fertilizers at depths of up to 2·5 ft. can be made practicable, then sub-soil water could be more effectively used by pastures, and irrigation needs reduced.

In crops, the influence of kinins on root growth, germination, bud growth and leaf-senescence (which affects the effective photosynthetic area) is noted, while revolutionary possibilities are opened up by complete chemical control of vegetation which permits 'minimal cultivation' and even brings into question the necessity for ploughing.

In animals, research on the metabolism of clinical disorders associated with calcium, phosphorus, iron, copper, magnesium, zinc and selenium illustrates the biochemical complexities of intensive animal production, while work at the Animal Diseases Research Association in Scotland on that elusive disease of sheep, scrapie, exemplifies the value of multi-discipline research. A link between reproduction research in humans and livestock is seen in the use, on pigs, of a temporary ovulation inhibitor which opens up the prospect of synchronized 'batch farrowing' by pig producers.

The Council (which now reports to the Department of Education and Science) is, of course, primarily concerned with scientific and engineering research. This may explain why there is no mention of the tentative, but potentially very important, link between scientific and farm management research through the creation, by multi-variable experiments, of the multi-dimensional input–output curves so badly needed for the effective application to farming of modern business mathematics.

The report concludes with administrative and financial data. The total spent each year by or on behalf of the Council is about £10 million in Great Britain. This excludes research at official husbandry farms, on farm management, by agricultural economists, by the official veterinary service, by the supporting chemical and engineering industries and by agricultural scientists at universities. Even if this group spent as much as the Agricultural Research Council, the total research expenditure on and in the agricultural industry would only be about 1 per cent of the value of its gross annual sales. In farming in the United Kingdom, productivity per man is increasing at about 7 per cent per annum—one of the highest rates in the national economy. What further contribution could agriculture make to national economic efficiency if research expenditure was doubled? A. N. Duckham

ANTIMICROBIAL AGENTS AND CHEMOTHERAPY

VARIOUS aspects of antimicrobial agents, infectious diseases, and chemotherapy were discussed during October 17–21, 1965, in the 237 papers and 11 round tables and conferences presented at the fifth Interscience Conference on Antimicrobial Agents and Chemotherapy—Fourth International Congress for Chemotherapy. This meeting was held in Washington, under the sponsorship of the American Society for Microbiology and the International Society for Chemotherapy, and was organized with the co-operation of the Infectious Diseases Society of America. 1,422 interested scientists attended this meeting; 228, representing 26 countries, came from outside the United States.

The Congress opened with addresses by Prof. E. B. Chain, Prof. S. A. Waksman, and Prof. J. F. Enders, discussing the past 25 years of antibiotic therapy and prospects for the future. This theme of reviewing the accomplishment of the past and problems of the immediate future was carried further in a round table on "Are New Antibiotics Needed?" organized by Prof. M. Finland. The consensus of the panel members, including Profs. W. M. M. Kirby, H. F. Dowling, A. C. Todd and L. P. Garrod, and Prof. E. B. Chain, Dr. Y. Chabbert and Dr. C. W. Pettinga, was that new and specialized antibiotics are still needed. There are many infections which are not adequately treated by the available antimicrobial agents and there is a need for a 'good' antifungal agent, a better anti-Gram-negative bacterial agent, and agents to treat a host of 'uncovered diseases' including the viral diseases and those caused by protozoa and other parasites. Other round tables were concerned with "Gram-negative Infections", "Antibiotic Assay Methods", "Bacterial Sensitivity Testing Methods", and the "Chemotherapy of Venereal Diseases". In each of these panel discussions, experts from many countries reviewed their findings in the particular subject being discussed, and presented new information on the prospects for the immediate future. The need for non-toxic and effective antibiotics in the treatment of Gram-negative infections, the fungal infections, and in venereal diseases was repeatedly emphasized.

Among the topics discussed at the 'informal discussions' were: practical methods for handling information on antibiotics and chemotherapy; the activities of the International Center for Antibiotic Information (Liège): antibiotic nomenclature; and ecological roles of antibiotics The following rules were proposed for choosing antibiotic names: (*a*) an antibiotic's name should be chosen so that, if it is later shown to be a member of a family, the root-name can be modified to show members of the related series. (*b*) The name should be based on chemical structure, and, except where the structure is known, the name should be based on the generic class of the producing organism. (*c*) The name chosen should be euphonious.

A symposium on the chemotherapy of tuberculosis (organized by Dr. G. Brouet, Paris) included discussion of experimental bases of chemotherapy (by Dr. F. Grumbach), therapeutic possibilities with minor antibacterial drugs in infections with *Mycobacterium tuberculosis* (Prof.

K. L. Radenbach), and the United States Public Health Service trials of isoniazid prophylaxis. In the latter, Mrs. Shirley Ferebee summarized the experience with trials involving 73,000 participants, and concluded that in the 4–9 years of observation after the prophylaxis year, isoniazid reduced the incidence of tuberculosis by 50 per cent in all trials.

Cancer chemotherapy was the subject of another symposium (convened by Prof. C. Heidelberger). Among the subjects reviewed were the antitumour antibiotics (by Prof. H. Umezawa), immunological approaches to host-tumour interactions (by Dr. M. Feldman), the relationships of pharmacology and cancer chemotherapy (by Dr. D. P. Rall, National Institutes of Health), and the present status of clinical cancer chemotherapy (by Prof. F. J. Ansfield). Of particular interest was Dr. Feldman's presentation of the value of the immunological approach in experimental cancer chemotherapy.

The pharmacology and pharmaco-kinetics of chemotherapeutic agents were discussed in a variety of the contributions. Of noteworthy interest was a discussion of the antibiotic absorption following otic administration as observed by M. J. Weinstein and colleagues (Schering Corporation). (This approach reminded the audience of Shakespeare's treatment of the subject in *Hamlet* (Act I, scene 5).) The pharmaco-kinetic discussions included experimental models, the logistics of chemotherapy, the pharmaco-kinetic studies using sulphonamides and ABOB, and protein binding studies. The latter subject was treated more fully in a symposium on penetration of drugs into tissues (convened by Prof. W. F. Verwey), where special attention was given to serum protein binding of penicillins and other drugs, the penetration of chemotherapeutic agents into cells, passage of drugs into and out of the central nervous system, and mechanisms of drug transfer across the placenta.

As more is known of the mechanisms of action of various antibiotics, it is possible to use these inhibitory agents as biochemical tools. Prof. J. T. Park led a symposium which discussed the use of chloramphenicol in the investigation of the synthesis of lysine peptides by enzyme systems, antibiotics as inhibitors of cell wall synthesis, the use of aminoglycoside antibiotics in studying the genetic code, and the antifungal antibiotics as agents in observing the physiology of moulds and yeasts.

The first day of the Congress was devoted to a series of papers on problems of infectious disease. These included: a discussion of endotoxin; clinical significance of the occurrence of various Gram-negative organisms; infections following cardiac surgery; a series of papers on Mycoplasma as infectious agents; and immunization using adenovirus vaccines and parainfluenza virus vaccines. New penicillins were discussed in other clinically oriented discussions, with special emphasis on cephaloridine in therapy of a variety of bacterial infections. The differences in the β-lactamases hydrolysing penicillins and those splitting cephalosporin *C* were summarized by Sabath and Abraham, who noted a zinc co-factor requirement for the latter, as well as differences in heat stability in these enzymes from *Bacillus cereus*.

The chemistry of antimicrobial agents was discussed in a symposium (organized by Prof. K. L. Rinehart, University of Illinois) and in a series of contributed papers. Among the especially noteworthy reports were:

(1) The presentation of the structure of the iron-containing antibiotic, ferrimycin A_1, and the disclosure that a 'minor change' of an amide group changes this from an antibiotic to a growth factor. (This work was done at the Federal Institute of Technology, Zurich, under the direction of Prof. V. Prelog.)

(2) A study of the structure-activity relationships among the depsipeptide antibiotics (with special reference to valinomycin) was summarized by Academician M. M. Shemyakin (Institute for Chemistry of Natural Products, Moscow), who concluded that there is a parallelism between their anti-fungal activity and their ability selectively to induce active K^+ transport in mitochondria.

(3) Proof of the structure of the antibiotic verrucarin *A* was used by Prof. G. A. Sim (University of Illinois) to demonstrate the usefulness of X-ray crystallography in determining the structures of antibiotics and other natural products.

(4) The mode of anti-tumour action of the copper-containing phleomycins, and the new antibiotics, bleomycins, was reported by Prof. H. Umezawa (Institute of Applied Microbiology, Tokyo) to involve inhibition of DNA synthesis as with pluramycin. On the other hand, the high molecular weight enomycin was found to have a selective action on ascites cells and was more rapidly absorbed by these cells than by normal cells.

(5) A series of antibiotics, the moenomycins, were described by Schmidt-Thome (Hoechst) as having the empirical formula: $(C_{70}H_{124}N_7O_{40}P)_n^1$. Hydrolyses showed the presence of: glucose; glucosamine; quinovosamine; phosphoric acid monoesters; a terpene-like carbon chain; and a chromophore. These antibiotics are active against Gram-positive bacteria. Very slow elimination was noted on subcutaneous administration, and blood levels of moenomycins were demonstrated 47 days after administration. The moenomycins have been widely tested as feed supplements, and were found more useful than the tetracyclines in growth promotion tests with broilers, pigs and calves.

(6) Kasugamycin, an aminoglycoside antibiotic, was originally selected on the basis of antifungal activity against rice blast disease. It was reported by Prof. H. Umezawa and Dr. T. Ichikawa (First National Hospital, Tokyo) to be useful in controlling *Pseudomonas* infections in clinical trials.

(7) Desdamine, desdamethine and ethesdamine are new antibiotics formed when *S*-methyl cysteine or *S*-ethyl cysteine was added to celesticetin producing fermentations.

(8) Everninomicin *B* is an antibiotic produced by *Micromonospora carbonacea*. It is active *in vivo* against Gram-positive bacteria.

(9) A group of antibiotics called the sugordomycins were described by Berger *et al.* (Hoffmann-LaRoche) as chemically related to the coumermycins, and having favourable *in vivo* potentialities against Gram-positive infections.

(10) Wiley (The Upjohn Company) reported on the identification of a cytotoxic agent *U*-20,904 as *cis*-β-acrylamidine.

(11) The structure of alazopeptin was reported by Patterson (Lederle Laboratories) to be L-alanyl-(6-diazo-5-oxo)-L-norleucyl-(6-diazo-5-oxo)-L-norleucine.

Most of the papers presented at this Congress will appear in *Antimicrobial Agents and Chemotherapy—1965*, which will be published in June 1966, by the American Society for Microbiology. The book will be distributed to all registrants at the meeting, and will be available from the headquarters of the Society, 115 Huron View Boulevard, Ann Arbor, Michigan.

Plans for the 1966 Interscience Conference on Antimicrobial Agents and Chemotherapy are already under way. This conference will be sponsored by the American Society for Microbiology and organized with the co-operation of the Infectious Diseases Society of America. The sessions will be held during October 26–28, 1966, in the Sheraton Hotel, Philadelphia. Among the topics which will probably be discussed in symposia and round tables are: identification of antibiotics; chemical modification of antibiotics; adverse reactions to drugs; chemotherapy under immunosuppressive conditions; epidemiology of antibiotic-resistant infections; and non-pharmaceutical uses of antibiotics. Further information on the meeting and abstract forms can be obtained from Mr. R. W. Sarber, executive secretary, American Society for Microbiology, 115 Huron View Boulevard, Ann Arbor, Michigan.

SUPERNOVA PHENOMENA IN OB ASSOCIATIONS AND COSMIC X-RAY SOURCES

By L. L. E. BRAES and J. W. HOVENIER
Observatory, University of Leiden, The Netherlands

WE wish to direct attention to the fact that most of the cosmic X-ray sources so far observed[1-3] are located close to OB associations, and that three of them are situated between associations and 'runaway' stars which originated from them (Fig. 1). In view of the probable relation between OB associations, 'runaway' stars and supernovae on one hand[4], and supernovae and X-ray sources on the other[1,5-8], it is tempting to suggest that supernova phenomena in these associations may be the origin of the X-ray emission. It is not necessary that these X-ray sources be associated with the particular supernova outbursts that released the 'runaway' stars. The presence of such stars should be regarded only as an indication of former supernova activity.

Most striking is the proximity of the strongest X-ray source, Sco*XR*-1, to the nearest association Scorpius II. Situated at $\alpha = 16h\ 15m$, $\delta = -15{\cdot}2°$ ($l^{II} = 359°$, $b^{II} = +24°$), its position is nearly midway between the centre of Sco II ($l^{II} = 341°$ to $2°$, $b^{II} = +10°$ to $+30°$) and the 'runaway' star ζ Oph, which originated from it $1{\cdot}1 \times 10^6$ years ago[4]. It has already been suggested that Sco*XR*-1 is a nearby object because it is the most intense source, at the highest galactic latitude. If identified with a supernova remnant associated with Sco II, it would indeed be a nearby object with a distance of 170 parsec (pc) (ref. 9).

The X-ray source Sco*X*-2, located at $\alpha = 16h\ 50m$, $\delta = -39{\cdot}6°$ ($l^{II} = 345°$, $b^{II} = +3°$), lies between the emission nebula *IC*4628 in the Sco I association ($l^{II} = 343°$ to $345°$, $b^{II} = +1°$ to $+2°$) and the 'runaway' star *HD*151397. There is some evidence that several supernova explosions did occur in this association[4], for which a distance of 1,800 pc is adopted[10].

Cyg*XR*-2 at $\alpha = 21h\ 43m$, $\delta = +38{\cdot}8°$ ($l^{II} = 88°$, $b^{II} = -11°$) is an X-ray source situated between the association Lacerta I ($l^{II} = 92°$ to $107°$, $b^{II} = -7°$ to $-20°$), at a distance of 600 pc (ref. 11), and the two 'runaway' stars *HD*197419 and *HD*201910 (ref. 4). Because of its relatively high galactic latitude the relation to Lac I seems probable.

In summary, these three X-ray sources lie near the apparent edges of the stellar associations, but since it is certain that the 'runaway' stars belong to the associations, some members may be beyond these edges. This fact, combined with the uncertainty in the adopted positions of the X-ray sources, makes it possible to regard them as association members as well.

Without considering Sco*XR*-1 and Cyg*XR*-2, we should now like to direct attention to the resemblance between the general distribution of the X-ray emission along the galactic equator[2], and that of associations and clusters of early-type stars within 2 kpc (ref. 12).

The complex of sources and the regions from which X-ray signals were clearly observed above the background between $l^{II} = 330°$ and $40°$ may be associated with the groupings of early-type stars in the Sagittarius spiral arm, at a distance of about 1·5 kpc. The gap in the distribution of X-ray emission between $l^{II} = 40°$ and $60°$ may correspond to the region between the Sagittarius and Orion arms. Finally, the emission from the Cygnus region between $l^{II} = 60°$ and $80°$ may originate from the Orion arm associations between 1 and 2 kpc from the Sun. If these identifications are accepted, the X-ray sources in the two regions mentioned would be at the same distance of about 1·5 kpc. If equal distances in general involve equal fluxes for X-ray sources, then the fluxes of the sources concerned would also be about the same and equal to that of Tau*XR*-1 (the Crab Nebula). This is indeed in accordance with observations[2].

Apart from Tau*XR*-1, no X-ray sources have been detected near the galactic equator between $l^{II} = 80°$ and $300°$. This may be partly due to the fact that the search

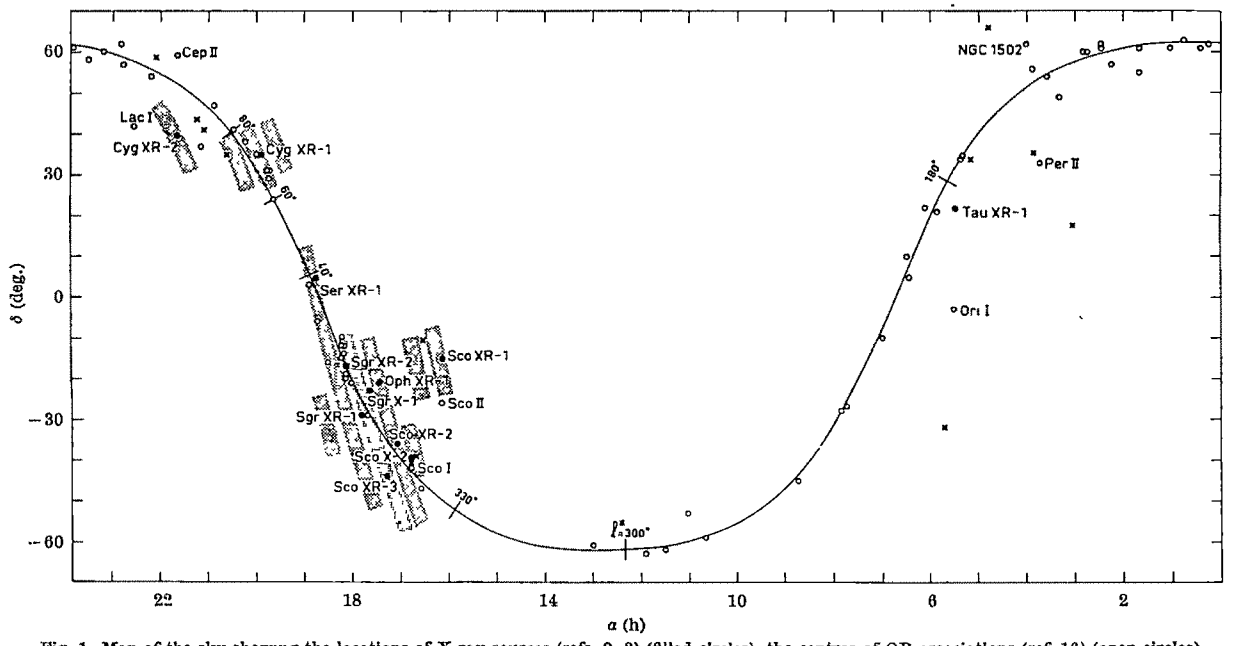

Fig. 1. Map of the sky showing the locations of X-ray sources (refs. 2, 3) (filled circles), the centres of OB associations (ref. 16) (open circles), and 'runaway' stars (ref. 4) (crosses). Shaded areas indicate regions in which X-ray emission in excess of the background radiation has been observed (ref 2). The full line is the galactic equator

for X-ray emission has not yet been made as thoroughly in this region as elsewhere. In addition, most of the associations between $l^{II} = 80°$ and 180° are in the Perseus arm, which is more than 2 kpc from the Sun, and therefore associated X-ray radiation might be too weak to be detected. Also the region along the galactic equator between $l^{II} = 180°$ and 300° is sparsely populated with nearby OB associations. Finally, between $l^{II} = 300°$ and 330°—where associations are missing—no search for X-rays has been made.

Provided that all supernova remnants in nearby associations emit detectable X-rays, which need not be true, X-ray emission would be expected in the direction of Orion I ($l^{II} = 207°$, $b^{II} = -18°$), from which three 'runaway' stars are known to have originated. Other nearby groups of early-type stars that are accompanied by 'runaway' stars, but apparently not by X-ray sources, are Cepheus II ($l^{II} = 101°$, $b^{II} = +5°$), *NGC*1502 ($l^{II} = 144°$, $b^{II} = +8°$) and Perseus II ($l^{II} = 161°$, $b^{II} = -16°$).

The distribution of X-ray sources over the sky can thus be explained by a relation with supernovae in associations within ~ 2 kpc. We shall now show that the observational data on their number, spectra and angular diameters may also be consistent with this picture.

Hayakawa *et al.*[6] suggested that in general the observed X-ray sources may be attributed to relatively nearby galactic supernovae. They found, by comparing the rate of supernova outbursts as derived by Hsi and Po with the number of observed X-ray sources, that the X-ray emission of a source should be appreciable for as long as $\sim 4 \times 10^4$ year. This was based on the assumption that these sources were not more distant than about 1 kpc. However, if we change this limit to about 2 kpc. as we do here, an X-ray lifetime of $\sim 1 \times 10^4$ year follows.

A supernova remnant may emit X-rays by several processes, but we shall limit our considerations to the thermal radiation of an optically thin hot plasma, since the spectra of the Sco*XR*-1 source and the sources in the region near the galactic centre can be fitted very well with a spectrum of such radiation if the temperature is $3{\cdot}8 \times 10^7$–$5{\cdot}8 \times 10^7$ °K (refs. 13 and 14). The 20–40 keV photons of the Crab Nebula found by Clark[15] may then be due to a high-energy tail in the distribution of electron velocities.

Using the results of Gould and Burbidge[6] and adopting a temperature $T = 5 \times 10^7$ °K, we find for the rate of loss of the free-electron kinetic-energy density 1×10^{-23} n_e^2 erg cm^{-3} sec^{-1}, where n_e is the electron density. Hence the cooling time may be defined as:

$$\frac{3kT}{10^{-23} n_e} \text{ sec}$$

where k is the Boltzmann constant. If this is taken to be 10^4 years we obtain $n_e = 5 \times 10^3$ cm^{-3}.

The X-ray flux of a source received on Earth is given by:

$$F = \frac{p n_e^2 V}{4\pi d^2}$$

where pn_e^2 is the X-ray emission (erg cm^{-3} sec^{-1}), V is the emitting volume, and d is the distance of the source. Taking the observed flux in the 1–10 keV range to be $F = 10^{-7}$ erg cm^{-2} sec^{-1}, and adopting $p = 9 \times 10^{-24}$ erg cm^3 sec^{-1} (ref. 6) and $d = 170$ pc, we find for Sco*XR*-1 an X-ray emitting volume $V = 1 \times 10^{51}$ cm^3. If this is to be thought of as a sphere its radius will be 2×10^{-2} pc, corresponding to an angular diameter of ~ 1′. This would be well within the upper limit of 7′ found for this source even if the volume were not exactly spherical.

The flux in the 1–10 keV range of the other sources is lower by about a factor of 10 than that of Sco*XR*-1, whereas in our opinion their distances are larger by about a factor of 9. Consequently, the difference in flux cannot be ascribed to a distance effect only, but could be due, for example, to the emitting volume of these more distant sources being larger. Other things being equal, their angular diameters would be smaller by a factor of about 4, which again is small enough to allow for the observational evidence.

We think that the existence of a hot plasma of the kind considered above in a supernova remnant cannot be excluded. The less so because, in the case of the Crab Nebula, Hayakawa *et al.*[8] have shown that the emitted 1–10 keV photons may be due to one or more hot condensations with $n_e \approx 10^3$ cm^{-3} and $T \approx 1 \times 10^8$ °K, having a total volume of ~ 10^{53} cm^3. These values do not differ very much from those considered in this article.

We conclude that there may be a close relationship between observed X-ray sources and supernova remnants in OB associations nearer than 2 kpc.

IONIZING RADIATION AND THE INTRACELLULAR OXIDATION-REDUCTION STATE

By DANA JAMIESON

Radiobiological Research Unit, Cancer Institute Board, Melbourne, Australia

SIGNIFICANT changes in activity of oxidases and other enzyme systems after exposure of animals or cells to ionizing radiations have been described by many investigators. However, many reports have also appeared which failed to confirm these changes in the same systems. For example, Warburg *et al.*[1] reported that 2,000 r. markedly reduced the rate of glycolysis in ascites tumour cells, while Coe *et al.*[2], using somewhat different incubation conditions, found no such effect in these cells. Barron *et al.*[3] reported inhibition of respiration and oxidation of substrates requiring sulphydryl enzymes in tissue slices of various organs, but Le May[4] found that the succinoxidase system of the rat kidney homogenates was unaffected by 400–800 r. Ashwell and Hickman[5] found no effect on

spleen succinic dehydrogenase or cytochrome oxidase after an LD_{90} dose of whole-body irradiation to mice, yet Fischer *et al.*[6], using rat spleen, reported the opposite result. More recently, significant decreases in Krebs cycle dehydrogenase systems were reported in liver and spleen of rats immediately following moderate doses of whole-body irradiation, and with increasing effect with time after irradiation[7].

Most of the investigations which demonstrated changes in the activity of respiratory enzymes were carried out hours, or days, after irradiation, by which time the cell population in the 'radiosensitivie' tissues (such as spleen, gastro-intestinal mucosa, thymus, lymph nodes) has grossly altered—and thus alterations in metabolic activity at such times are of dubious importance in evaluating the primary effects of irradiation at the cellular and sub-cellular level. In addition some of the observed effects on tissue enzymes after whole-body exposure have later been ascribed not to direct radiation effects on the tissues *per se* but to indirect (abscopal) mechanisms—since local irradiation may fail to produce the changes which result from whole-body exposures[8,9].

Oxidative phosphorylation studies after irradiation are also difficult to interpret in terms of primary effects. Thus Potter and Bethel[9,10] reported a depression of oxidative phosphorylation in rat spleen, confirmed by van Bekkum[11], while other workers interpret such changes as most likely due to preparation artefacts[12]. For the irradiation of isolated mitochondria *in vitro*, fairly general agreement exists that no effect on oxidative phosphorylation is produced by doses up to 30 krads[10,11,13–15].

Recent detailed investigations on the respiration and phosphorylation in isolated mitochondria after irradiation *in vitro* show that succinate or β-hydroxybutyrate oxidation was not altered by radiation doses of less than about 100 krads, while oxidative phosphorylation was somewhat more sensitive[15]. The study of coenzyme-levels, principally NAD and NADH, after irradiation has led to similarly conflicting reports for the different systems investigated[16,17].

The various contradictory reports described here cover only a limited amount of work in this field, but serve to exemplify the difficulties involved in an attempt to determine whether irradiation can primarily disturb respiratory metabolism and whether such effects contribute to cellular radiation damage. As pointed out by Dale[18] and Krebs[19] in discussing the effects of irradiation on cell metabolism, a depletion or activation of stored enzymes in a cell may not be a true indication of changes in the functional capacity of the enzyme. Changes in levels of enzymes which are not essential control sites of cellular function may also cause little disturbance of such normal function[19]. Indeed, Dale[18] asks: "Can one expect from an analysis of tissue extracts or homogenates irradiated as such, or made from irradiated tissues, any answer to the question of the participation of enzymes in biological radiations effects ?".

A different approach to this problem was used in the present investigation where the level of reduced pyridine nucleotides was monitored during and up to 1 h after irradiation in several organs of the rat *in vivo*, and in ascites cell and thymocyte suspensions *in vitro*. Continual monitoring of the intracellular oxidation-reduction state as reflected by the ratio of oxidized pyridine nucleotides (NAD and NADP) to reduced pyridine nucleotides (NADH and NADPH) was possible with the fluorometric techniques developed by Chance *et al.*[20–22]. Decreases in dehydrogenase activity cause oxidation of NADH, while inactivation of the electron transport chain between pyridine nucleotides and the final electron acceptor, oxygen, produces reduction of pyridine nucleotide[23]. This technique can provide a continuous monitor of 'functional' activity of the respiratory system in the intact cell, thus removing tissue preparation artefacts and also allowing measurement of any changes in the system during the actual irradiation of cell suspensions or tissues.

The apparatus used for *in vivo* fluorometric measurements was as described by Chance *et al.*[24]. Rats (150–220 g Canberra Black males) were anaesthetized with 1·2 g of urethane per kg body-weight, a trachael cannula inserted, and the organ under investigation exposed. As most of the fluorescence measured *in vivo* is emitted from the exposed surface of the tissue, to a depth of about 0·5 mm[24], large doses of radiation could be given in a short time, by using a Phillips beryllium window source operated at 50 kV and 2 m.amp, with no added filtration. The remainder of the animal was lead-shielded during irradiation. For cell suspension work the fluorometer was mounted above a small gassing (pressure) chamber, mounted over a magnetic stirrer, as described by Chance *et al.*[25].

In vivo experiments. The tissues investigated were kidney and ileum, the latter with either serosal or mucosal surfaces uppermost. The kidney has previously been used for the study of *in vivo* oxidation-reduction states[20,21,24] and its responses are well characterized. Thus increases in fluorescence, due to pyridine nucleotide reduction, are observed in the aerobic–anaerobic transition *in vivo* and similar fluorescence responses to inhibitors of electron transport are obtained in the kidney[20], as have been shown to occur in isolated mitochondria[26]. The use of ileum for such fluorometric measurements has not been reported previously but it proved to be a very suitable tissue; large consistent fluorescence responses were obtained with changes in the steady state, and the emission spectrum of the isolated perfused tissue under aerobic or anaerobic conditions was similar to that of the other organs previously reported[21]. Cyclic changes in fluorescence were often observed in the ileum for both mucosal and serosal surfaces, but particularly for the latter. Their origin has not yet been investigated but, by analogy with results obtained with skeletal[27] and cardiac muscle[28], it is possible that they are due to cyclic activity of the intestinal smooth muscle, such as pendulum movements. Examples of such cyclic activity, together with the responses of the ileal smooth muscle *in vivo* to injections of amytal and sodium sulphide, are shown in Fig. 1. It can be seen in Fig. 1*A* and *B* that anoxia, amytal and sulphide cause approximately the same increase in fluorescence, due to pyridine nucleotide reduction, and the responses are similar to those described for kidney *in vivo*[20]. Results in this respect for the mucosa were similar. Thus ileum behaves in a 'predictable' fashion. Liver, particularly in the aerobic–anaerobic transition[29],

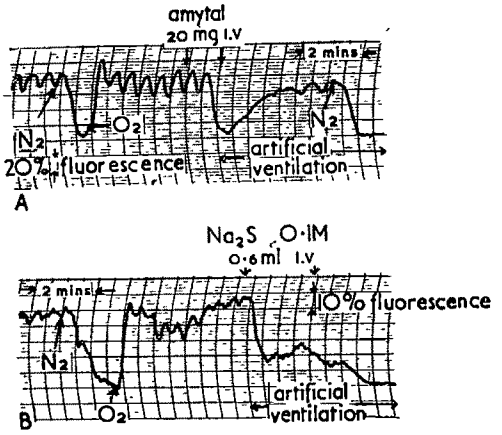

Fig. 1. *A*, Comparison of the effect of anoxia and an intravenous injection of amytal on pyridine nucleotide fluorescence in rat ileum (serosa) *in vivo*. *B*, Effect of sulphide in causing pyridine nucleotide reduction. Fluorescence increase due to pyridine nucleotide reduction in this and all subsequent figures corresponds to a downward deflexion of the trace. The calibration fluorescence, 20 per cent in the ileum in *A* and 10 per cent in *B*, is an arbitrary value, with 100 per cent corresponding to the initial level of fluorescence (dark current as zero) from the aerobic tissue, in this and the following illustrations

is less predictable, and unfortunately spleen, which has often been investigated for radiation effects, was found unsuitable due to the high concentration of haemoglobin in this tissue causing excessive absorption of the fluorescence signal. Therefore, *in vivo* irradiation investigations were confined to kidney, smooth muscle of the ileum and gastrointestinal mucosa. The dose-rate was usually 6–12 krads per min. Before irradiation one or two anoxic cycles were recorded by connecting the tracheal cannula to a nitrogen atmosphere. Immediately after irradiation another anoxic cycle was recorded, and such anoxic challenges were repeated every 15–20 min. Control experiments showed that most preparations gave reproducible responses for at least 1 h, especially if the tissue was kept moistened with warm saline and if the anoxic cycles were repeated at not over-frequent intervals. Some preparations remained apparently unchanged for up to 3 h, but sometimes fluorescence loss was observed in controls after 1 or 2 h, and thus it was considered that evaluation of the results should be restricted to 1 h after irradiation.

A typical record from the ileum is shown in Fig. 2. In this experiment cyclic activity was not seen. Nitrogen inhalation caused a large fluorescence increase, with a return to normal intensity preceded by a slight oscillatory response on ventilating the animal with oxygen, the oxygen being substituted by air as soon as spontaneous respiration was re-established (Fig. 2*A*). Irradiation with 12 krads produced no effect (Fig. 2*B*) and an anoxic cycle a few minutes after irradiation was essentially similar to the control responses prior to irradiation (Fig. 2*C*). Fig. 2*D* shows that even at 1 h following irradiation the fluorescence signal was similar to that before irradiation. This lack of effect of irradiation was seen in a total of fifteen experiments on this tissue with tissue exposures up to 100 krads. (High dose rates above 25 krads/min often produced a non-reversible decrease of the aerobic fluorescence amounting to 10 per cent–15 per cent when a total dose exceeding 50 krads was delivered. This decreased fluorescence with such large doses at high dose-rates does not, however, appear to be a biochemical oxidation of NADH since the magnitude of the fluorescence increase in the aerobic–anaerobic transition is unaltered, that is, the whole level of fluorescence has decreased. Similar effects were also observed in irradiation of a standard gelatine filter under the same conditions. This effect, therefore, appears to be a direct chemical phenomenon, such as depolymerization of macromolecules.) Experiments using ileal mucosa gave a similar result, and in preparations showing cyclic activity the latter was not abolished by doses up to 50 krads of X-radiation.

Experiments with kidney were performed in the same way, but in addition one or two flexible 50 mμ gold electrodes to record tissue pO_2 were inserted, to lie beneath the kidney capsule. The technique of measuring tissue pO_2 with such electrodes has been described previously[30,31].

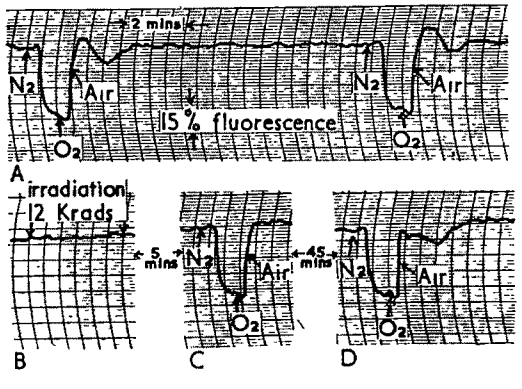

Fig 2. The effect of irradiation on the rat ileum (serosa) pyridine nucleotide fluorescence *in vivo*. Calibration figures as in Fig. 1

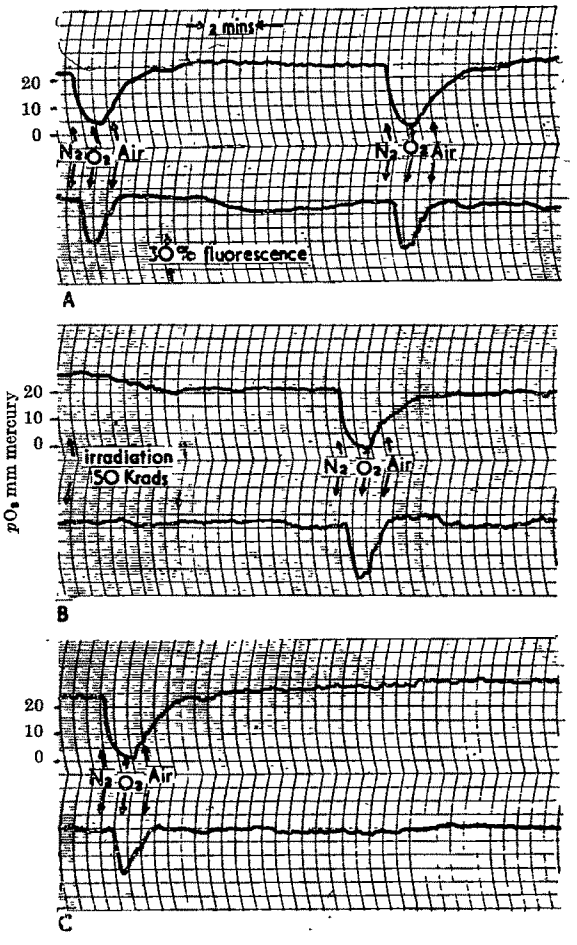

Fig. 3. The effect of irradiation on rat kidney pO_2 and fluorescence. The top trace in each section is the oxygen tension, the lower trace fluorescence. The figure is explained in the text; calibrations of fluorescence are as in Fig. 1. *A*, Before irradiation; *B*, during and immediately after irradiation; *C*, approximately 1 h after irradiation

The results obtained are illustrated by the example in Fig. 3. When nitrogen was inspired the pO_2 rapidly fell and when a level of only 1–2 mm mercury of oxygen was recorded, the fluorescence began to increase, to attain a maximum when the oxygen electrode recorded a near-zero pO_2 value. Chance[29] has calculated that the intracellular pO_2 for pyridine nucleotide reduction is of the order of 0·5 mm of mercury. On returning the animal to oxygen, followed by air, the fluorescence recovered more rapidly than the oxygen tension, and after some minutes equilibrium was restored. This control cycle was repeated and the tissue was then irradiated with 50 krads at a dose-rate of 12·5 krads/min. No effect was seen on the fluorescence trace but a slight decrease of oxygen tension occurred. Some minutes later nitrogen breathing resulted in a normal response, similar to the pre-irradiation effect, and 1 h later the responses still remain unaltered. The slight decrease in pO_2 during irradiation was seen consistently on doses of irradiation exceeding 50 krads. In some experiments with the kidney where pO_2 was recorded, 0·5 mm aluminium filtration was used to obtain better depth dose, but failed to affect the results. The magnitude of the radiation-induced pO_2 effect varied but never exceeded a 30 per cent decrease even with the highest doses of radiation used (100 krads). This decrease in tissue pO_2 could be due to local vascular effects, or to increased oxygen consumption through uncoupling of oxidative phosphorylation[10,11]. Partial uncoupling *in vivo* may occur without significant changes in pyridine nucleotide levels if the tissue is already in an active metabolic state (State 3) as discussed by Chance *et al.*[20]. It is also

possible that the decrease in pO_2 results directly from oxygen utilization due to the high radiation dose[32].

Ascites Lettrè hyperdiploid line tumour cells. For the irradiation of single-cell suspensions tumour cells were gathered from the intraperitoneal cavity of mice 5–6 days after inoculation with 10^6 cells, the cells from each mouse centrifuged gently, washed twice with buffered medium (*tris* buffer 0·005 M; sodium monohydrogen phosphate, 0·005 M; sodium chloride, 0·12 M; potassium chloride, 0·006 M; magnesium sulphate, 0·001 M; calcium chloride, 0·002 M) and then re-suspended in a volume of the same medium equal to the packed cell volume.

70 µl. of such a suspension was placed in a small cuvette as previously described[25]. All experiments were done at a room temperature of 26°–28° C. After establishing a control aerobic–anaerobic transition in the gassing chamber the sample was removed from the chamber for irradiation, as the quality of radiation was too soft for penetration through the thick-glass window of the gassing (pressure) chamber. A 0·5 mm aluminium filter was used and the dose was measured in 2 mm maximum depth of fluid with constant stirring during irradiation. The fluorometer was not moved, so that the sensitivity remained unaltered during the experiment. The dose in the vessel used was measured with a modification[33] of Fricke's chemical dosimetry technique[34]. Results of a typical experiment are shown in Fig. 4. Panel (*A*) shows the control response to anaerobiosis. About 30 sec after flushing with nitrogen an increase in fluorescence began, reaching a plateau in about 1·5 min. On flushing with oxygen re-oxidation of pyridine nucleotides immediately resulted and equilibrium was restored within 1 min. The cells in their container were removed from the chamber, and irradiated in air with 10 krads (dose-rate 2·5 krads min^{-1}). Rapid stirring was maintained during irradiation. Immediately after irradiation the cells were replaced in the gassing chamber and another anaerobic–aerobic transition recorded (Fig. 4*B*). The cycle recorded was similar to the pre-irradiation response. At room temperature, 1 h later, the response was still unaltered. Similar experiments were performed using three different samples of ascites tumour cells, and radiation doses of 1, 2, 5, 10 and 20 krads were delivered to aliquots of each sample. In addition, in separate experiments, the fluorometer was so positioned that the fluorescence signal could be recorded during irradiation. No definite effects of irradiation were observed in any experiment.

Thymocytes. Thymocytes prepared from Canberra black rats of 150–200 g weight were washed once in the medium already described and the packed cells re-suspended in an equivalent amount of medium. They were then subjected to the experimental methods already described for ascites cells. Thymocytes initially gave a somewhat weaker fluorescence signal than ascites cells, which is not unexpected in view of Scaife's finding that most of the pyridine nucleotide in these cells is present as NAD[17].

A small but definite oxidation consistently preceded the reduction of pyridine nucleotides in the aerobic–anaerobic transition of thymocytes (Fig. 5). The cause of this initial decrease in fluorescence is not known. Irradiation of thymocytes with 5 krads produced no change during irradiation (Fig. 5*B*), immediately after irradiation

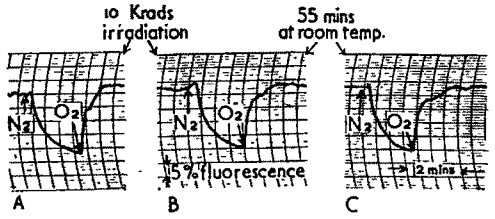

Fig. 4. Aerobic–anaerobic transitions in ascites tumour cells before (*A*), several minutes after (*B*) and 1 h (*C*) after 10 krads irradiation

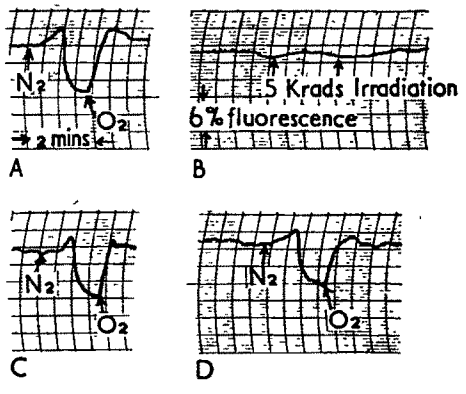

Fig. 5. Isolated thymocytes before (*A*), during (*B*), immediately after (*C*) and 1 h (*D*) after irradiation with 5 krads

(Fig. 5*C*), and little effect even 1 h later (Fig. 5*D*). Doses of 1, 2, 5 and 10 krads were given to each of three samples of cells, and the results were similar to those shown in Fig. 5. After doses of 20 krads there was again no immediate effect but the response to nitrogen, 1 h post-irradiation, showed some diminution. Nigrosin counts showed only 2–3 per cent non-viable cells in cells studied before or immediately after irradiation. The nigrosin dead cell count increased to 9–10 per cent after thymocytes were left at room temperature for 1 h, whether irradiated or not. Pyknotic counts showed only a slight increase between fresh cells and cells examined 1 h later (2–4 per cent respectively). Irradiation did not affect the pyknotic count at 1 h after irradiation.

The results reported here demonstrate the rather striking insensitivity of the electron transport chain, including dehydrogenases and associated coenzymes, to X-irradiation. The intracellular oxidation-reduction state was virtually unaltered even when massive doses of radiation were administered, and up to 1 h post-irradiation electron transport reactions appeared to function normally. Thus changes reported in respiratory enzyme-levels or coenzymes, assayed at later times after irradiation, appear to depend on other forms of cellular damage and are not a primary radiation lesion. Changes, also, in enzyme and coenzyme levels investigated by *in vitro* assay methods may not be a true reflexion of their functional activity in the cell. The present investigation includes several tissues of varying radiosensitivity—from kidney and smooth muscle, generally classed among 'radioresistant' tissues, to gastro-intestinal mucosa *in vivo*—a 'radiosensitivie' tissue and rapidly dividing ascites cells *in vitro* of known high 'radiosensitivity'. Non-dividing thymocytes are of special interest in that these cells have been shown to be destroyed by small radiation doses insufficient to cause the destruction of most other cells in the mammalian body[35–38]. This death is 'degenerative' rather than the result of mitotic aberrations induced by ionizing radiations, and pyknosis can be observed in thymocytes and small lymphocytes within a few hours of irradiation. The pyknotic death of these cells, which becomes evident about 3 h after irradiation, is a peculiar response, since high doses of radiation (> 5 krads) apparently inhibit the development of pyknosis[36,37]. Shrek[36] regards this high-dose effect as one of 'delayed fixation' of cells. However, irrespective of whether low doses or many times supra-lethal doses of radiation were received by these cells, their respiratory function remained unaltered.

Laser[39–41] has produced evidence for the inactivation of some electron transport components (namely, cytochrome *c* and riboflavin) by X-irradiation *in vitro*. Large radiation exposures, in excess of 10 krads, were used to produce these effects and the reaction recorded showed a reversed

'oxygen effect'; with greater damage resulting from irradiation under anaerobic conditions, where these components are in the reduced state. However, the observed effects would seem of little radiobiological significance in explaining irreversible radiation damage to cells, for with very few exceptions both *in vivo* and *in vitro* biological and chemical systems show a positive oxygen effect, and cellular cytochrome *c in vivo* would under normal physiological conditions be almost fully oxidized[42]. The lack of an oxygen effect and the radiation protection afforded by cyanide in the bacteria used by Laser[9] remains paradoxical, and is certainly not a universal phenomenon in radiation damage to micro-organisms[43].

The results of Barron *et al.*[44] and Scaife[17] are particularly relevant to the present investigation. Barron has shown that irradiation of NAD in solution has little effect and no conversion to NADH occurs even with doses of 100 krads, but NADH in solution is fairly sensitive to irradiation, with 1 krad producing measurable effects. This is in contrast to *in vivo* effects, where very high doses of irradiation fail to cause NADH oxidation, verifying that binding of substances and the presence of cellular components may greatly modify their radiosensitivity, as demonstrated by Dale[18].

Scaife[17] assayed NAD-, NADP- and NADH-levels in rat thymus and isolated thymocytes before and after irradiation. One h after irradiation a decrease of NAD content had occurred in the thymus and isolated thymocytes which increased with time, with no corresponding effect on NADH. Such NAD loss without reduction to NADH can occur without affecting the fluorescent signal recorded in these experiments, which is a measure of NADH and its changes during transitions between various metabolic states. Probably either the stored NAD from a different cellular compartment (nuclear ?) or defective NAD synthesis is responsible for the reduced NAD content of thymocytes assayed after irradiation. Indeed, Scaife concluded that the most probable explanation of his results was that NAD is released from bound NAD within the cell after irradiation, and metabolically destroyed—a view in keeping with the enzyme release theory of Bacq and Alexander[45].

A further aspect of this investigation concerns the theory that the effects of ionizing radiations and high-pressure oxygen are produced by similar mechanisms, a theory proposed by Gerschman *et al.*[46] and elaborated by Laborit and Brue[47]. Considerable evidence exists which fails to support this theory[48], which states that similar oxidizing free radicals may be produced by hyperbaric oxygen and ionizing radiations, and cause similar intracellular lesions. The present work fails to support this hypothesis. The lack of effect of irradiation on pyridine nucleotide fluorescence contrasts sharply with the immediate effect of hyperbaric oxygen on the intracellular oxidation reduction state, described previously for various systems, including rat kidney, brain, liver, ascites tumour cells, isolated mitochondria, and succinoxidase particles[25]. The same effect of high oxygen pressure was found also in rat thymocytes in this investigation and is illustrated in Fig. 6. If indeed 'oxidizing free radicals' are the primary cause of cellular lesions induced by radiation and high-pressure oxygen respectively, then their reaction with cell components must occur at different loci, with electron transport reactions being particularly susceptible to high-pressure oxygen but, as shown in the present investigation, particularly resistant to ionizing radiations.

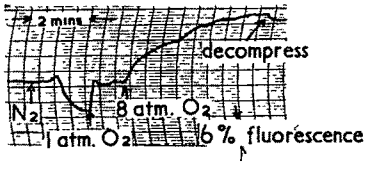

Fig. 6. The response of pyridine nucleotides to hyperbaric oxygen. After a typical fluorescence increase in anaerobiosis the cells are re-oxygenated, then when equilibrium is restored rapidly pressurized to 8 atm. absolute in oxygen. An immediate decrease in fluorescence occurs indicating oxidation of reduced pyridine nucleotide, and reaches a plateau in about 4 min

I thank Prof. Britton Chance for supplying me with the fluorometer, and the gift of the gassing chamber, used in this investigation. I also thank Prof. Chance and many members of the Johnson Foundation, Philadelphia, for their help with the techniques involved. Dr. H. A. S. van den Brenk is thanked for histological examination of the thymocytes, his advice and criticism of the manuscript.

CRYSTALLIZATION OF PETROLEUM WAXES

By Dr. B. F. BIRDWELL
Department of Petroleum Engineering, Louisiana State University, Baton Rouge, Louisiana
AND
Prof. F. W. JESSEN
Department of Petroleum Engineering, University of Texas, Austin, Texas

THE nature of petroleum wax crystals is often important in both the processing and the end usage of these waxes. Likewise, the modification of the normal crystal habits is practised in a number of applications. Typical of these are the use of pour point depressants in lubricants, the use of modifiers in refinery wax filtrations, the use of modifiers to control the physical properties of commercial waxes, and the use of 'paraffin inhibitors' in the production of crude oils. This article reviews the present knowledge of this topic as reflected by the literature.

Crystal Habits of Pure Hydrocarbons

X-ray investigations of pure hydrocarbons have revealed that *n*-paraffins crystallize in triclinic, monoclinic, hexagonal or orthorhombic crystal systems, depending on the particular hydrocarbon and the temperature[1–5]. The reasons for assumption of one of these symmetry relations by the crystals have been discussed by Kitaigorodskii[2] on the basis of even–odd carbon numbers and packing (or stacking) efficiencies.

The temperature relation concerns a solid-state transition that many (but not all) the *n*-paraffins exhibit[2,6–10], and involves symmetry and packing changes associated with rotation or non-rotation of the molecules about their chain axes.

In all cases, the *n*-paraffins crystallize with the chain axis parallel to the crystallographic *c*-axis. In the hexagonal and orthorhombic lattices, this implies that the chain ends will all lie in a plane joining one layer of the long molecules to the next layer. Hence, the bonds joining the layers will be different from those joining the members of each layer. Such an arrangement is typical of the platy minerals (such as mica and clays). It is not surprising, then, that pure *n*-paraffins exhibit a tabular or platy crystal habit, the most common forms of which are thin hexagonal or rhombic plates[7,11].

There is much less crystallographic information in the literature on the iso-paraffins than on the *n*-paraffins. No X-ray data for these hydrocarbons were located. Investigations using polarized light microscopy[7,12] indicate that pure branched chain paraffins also predominantly crystallize as plates with an orthorhombic lattice, with some apparently crystallizing in monoclinic or triclinic plate forms. In one case it has been reported that the pure naphthenic waxes crystallized primarily as orthorhombic plates, with one compound crystallizing in rectangular plates apparently belonging in the tetragonal system[7]. All naphthenes investigated, however, possessed long alkyl side-chains.

X-ray data suggest that most of the pure aromatic waxes crystallize in the monoclinic system with a few taking the orthorhombic forms[2,13]. Plates were observed as the predominant forms in a limited investigation[7].

Crystal Habits of Refined Waxes

The highly refined petroleum waxes that contain high proportions of *n*-paraffins exhibit crystal forms and sizes very similar to those characteristic of the pure *n*-paraffins[8,12,14–16]. This indicates that the *n*-paraffin waxes are fairly compatible with each other and even tolerate small amounts of other types of hydrocarbons without drastic modification of the crystal habit. Edwards[14,17] suggested that this is because the *n*-paraffins tend to form continuous series of solid solutions over a fairly wide range of chain-lengths. He also suggested that the crystal lattice is largely controlled by the more numerous *n*-paraffins, and the hexagonal and orthorhombic lattices seem to be able to tolerate solid solutions better than the other crystal systems. Others also maintain that *n*-paraffin mixtures crystallize as a series of solid solutions[3,14,17–19], although some believe that the refined microcrystalline waxes, containing considerable amounts of iso-paraffins and naphthenes (and possibly aromatic resins), form systems exhibiting eutectic compositions[8,16].

One group has reported that they could not use X-ray diffraction as a means of determining the iso-paraffin content of refined petroleum waxes, since the moderately high iso-paraffin content fractions investigated gave crystallographic data very near that of pure *n*-paraffins[11]. At very high iso-paraffin percentages, however, the crystal forms became almost exclusively ribbon or blade-like, rather than rhombic plates.

Less highly refined petroleum waxes, generally having low *n*-paraffin content and a wide variety of impurities, almost never crystallize as plates, but rather produce crystals described as 'needles'[6,8,12,20,21] and 'malcrystalline'[12,22,23] forms.

Mechanisms of Crystal Habit Modification

A review of several texts and a number of papers on the general topics of crystal nucleation, growth and habit modification revealed that these subjects are far from well understood.

Supersaturation is a basic requirement for nucleation. Some impurities permit only minute supersaturation before spontaneous nucleation occurs, and others necessitate quite large supersaturation before nucleation is possible; yet we can seldom predict how a given impurity will affect the crystallization of a particular solution.

Many theories of crystal growth have fallen into disfavour through the years; present-day theories, however, still cannot explain many crystallization phenomena, and continue to be controversial.

The control of crystal habit modification is desirable in many industries, and there is a wealth of reported information in the literature concerning specific instances; however, a general theory of habit modification has not been possible. Indeed, Wells[24] points out that, "The discussion of abnormal crystal growth implies that we know what is meant by normal growth, but this is far from being true".

The most controversial of the modified forms the petroleum waxes assume is that of 'needles'. Some of the earliest research workers in this field ascribed the crystallization of petroleum waxes in the needle form (rather than plates) to the effect of high viscosities of the solvent media[25,26]. Others considered that high rates of cooling caused the needle forms[7,21]. The temperature of crystallization and its relation to the transition temperature and melting-point of the wax was assigned importance by some; crystallization above the transition point was supposed to cause needle forms, and crystallization below the transition temperature was believed to create plates[6–8]. One group of investigators considered that there were simply different homologous series present in the waxes and that some crystallized as plates, some as needles, and some as

malcrystalline masses[12,27]. Others considered that hydrocarbons other than *n*-paraffins were indeed present, but that they caused needle formation through their action as impurities rather than imposing their form as 'needle waxes'[7,20,23,28]. Still others agreed that impurities were the cause (these impurities could be even other *n*-paraffins), but that the mechanism involved was curling of stressed plates to form 'needles' of oval or rounded cross-section[14,29–31].

Curling of the plates to form needles appears to be a real phenomenon; the origin of the stresses responsible for the curling is still controversial, however, and there are a number of reports of the formation of needles which cannot be explained by the curling mechanism.

It seems probable that the milder modifications of the plate forms, such as rounded and irregular corners, notched ends and truncations, are the result of hindered ordering in the development of the crystal. That is, the *n*-paraffin molecules of different chain-lengths do not have sufficient time during the crystallization to arrange themselves in the most efficient manner; the iso-paraffins and naphthenes similarly are caught up in the lattice or adsorb on the crystal faces before they can be displaced by the *n*-paraffins. As a result, many deformities and dislocations occur in the lattice structure, and the 'normal' geometric habit is not always completely obtained.

It would be expected, on the basis of this postulate, that modifications would occur increasingly with both (*a*) the concentration of components other than *n*-paraffins (or range of *n*-paraffins), and (*b*) the rate of crystallization. Increased malformation of plate crystals with increased rates of cooling has been reported even for pure hydrocarbons[7]; similarly, a gradually increasing degree of plate modification due to increased amounts of non-normal paraffin content at the same rate of cooling has been demonstrated[14].

The solvent itself can be considered an impurity. The ease with which the solvent molecules can diffuse away from the area immediately surrounding the growing crystal will affect diffusion of the wax molecules toward the wax crystal, and could thus cause disorder at high rates of crystallization. This probably explains the viscosity effects on wax crystal habit that have been reported[25,26]. That the chemical nature of the solvent will also effect mild modification also has been reported[23,27]. Further, adsorption of a solute is known to differ even from solvents of identical solubility for the particular solute[32], and the solvent itself is often appreciably adsorbed[33]; thus, it is to be expected that the solvent will play at least a minor part in the crystal modification mechanism.

The tendency toward disordering may offer an explanation for the dislocation spirals and rosette aggregates formed[34]. Indeed, the dislocation spirals themselves may be necessary for the crystals to grow at all in thickness, since two-dimensional nucleation on the lamellae surfaces would be expected to occur with difficulty[35]. The frequent occurrence of wax crystals with features that appear to be associated with twinning operations again suggests that lattice dislocations are an important mechanism.

Concentration of impurities alone does not explain all the crystal modifications, as equal concentrations of different impurities quite often produce strikingly different results. A plausible explanation for this difference would seem to lie in specificity of adsorption of the additives, although this effect surely would not be as im[illegible] as with the habit modification of [illegible] even those containing polar mol[illegible] of the *n*-paraffin plate crystals [illegible] packed CH_3 groups, while th[illegible] are composed of CH_2 g[illegible] surfaces of the plate edges), but gave contact angles of 25°–46° on the basal (001) faces of *n*-hexatriacontane plate crystals. Gutsalyuk and Yatsenko[43] have observed that mono- and bi-cyclic aromatic compounds selectively adsorb on to paraffin wax from cracked residues. Indeed, the adsorption of alkyl-aromatics on to paraffin wax crystals has been postulated for many years in connexion with the pour point depression of lubricating oils[44–49].

On the basis of this evidence, it would seem reasonable to presume that condensed ring aromatics, such as naphthalene and anthracene, would adsorb on to the 'edge' surfaces of the wax plates and provide sufficient bulk to retard the accretion of paraffin wax molecules on to these surfaces. Recently, however, experiments by one of us[34] have indicated that a number of aromatic compounds have virtually no effect on the particular wax crystals studied, and certainly did not 'stunt' the plates by inhibiting their growth on the (110) faces (plate edges).

It would appear, then, that the adsorption-type aromatic additives are of questionable value in modifying wax crystals, unless they possess the long alkyl side-chains characteristic of the well-known alkyl-aromatic pour point depressants. One should note, however, that Lorensen[48] found that a biphenyl–isopropyl ether reaction product (containing no long side-chains) exhibited mild pour depressant qualities, although he did not describe the crystal forms produced in the presence of this additive.

The most severe modifications observed on the wax crystals, commonly called malcrystalline forms, have received only minor comment in the wax refining literature. Ferris and Cowles[12] believed that these malcrystalline forms were simply due to the presence of 'mal-type waxes'. Clarke[7], however, showed that they could be obtained even in pure hydrocarbons of *n*-paraffin, iso-paraffin, naphthenic, and aromatic types under conditions of very rapid cooling. He suggested that these malcrystalline forms were associated with high supersaturation. Few other explanations are offered in the literature, although the malcrystalline forms are generally associated with the most impure wax fractions, for example, petrolatums or distillation residues. Some have postulated that these forms are clusters of ordinary wax crystals cemented together by a nucleus of naturally occurring aromatic resins or asphaltic particles[50,51]. This has also been implied by others, but such a mechanism is not compatible with that involved in Clarke's work with pure hydrocarbons.

Recent work by one of us[34] has shown that the presence of asphaltic and resinous impurities definitely promotes these malcrystalline forms. It is believed, however, that they promote these forms by causing the wax to grow dendritically, rather than serving as nucleating or cementing agents. Close examination of photomicrographs of malcrystalline forms in the literature indicates that almost all represent dendritic growth.

There have been many theories of dendritic crystal growth presented, but most of them agree that one of two causes are generally present: a rapid crystallization rate, or high-impurity concentration. The explanation for the characteristic branching is usually that the crystal must rapidly change growth directions to avoid the localized accumulation of (*a*) heat of crystallization under rapid, extreme cooling[36], or (*b*) impurity concentration under high-impurity conditions and/or high supersaturation[52].

It see[illegible]tically reasonable, then, that malcrystalline [illegible]duced on pure substances [illegible]y high rates of cooling, or [illegible]gh-impurity concentrations [illegible]ooling; hence the data in [illegible]onflicting.

[illegible]for dendritic growth

nucleate or promote growth in new directions. A second is the formation of foliated dendrites through a mechanism involving impurities and screw dislocation growth, as proposed by Gorodetsky and Saratovkin[53].

WINE TANNINS—ISOLATION OF CONDENSED FLAVONOID PIGMENTS BY GEL-FILTRATION

By T. C. SOMERS

Australian Wine Research Institute, Glen Osmond, South Australia

THE molecular size of polyphenols is generally considered to be the most important factor in determining tanning activity, astringency, and also the inhibition of enzymes by such compounds[1,2], the term 'tannin' being best reserved for those phenolics of sufficiently high molecular weight (> 500) to have such properties[3]. However, no data on molecular size of tannins are available except for that concerning several oligomers of leucofisetinidin which were isolated from black wattle heartwood by counter-current extraction and two-dimensional paper chromatography[4]. The lack of a satisfactory procedure for routine isolation of condensed tannins from plant materials has greatly hampered progress in this field.

Monomeric flavonoids are conveniently isolated and purified by cellulose and polyamide chromatography, but highly polymerized polyphenols are irreversibly adsorbed on these materials. Consequently, the analysis of tannins has depended on examini[illegible] reactions which have some[illegible] structural features, as in t[illegible] glucinol residues and the e[illegible] content by acid convers[illegible] reasons, little is kn[illegible]

This article reports some preliminary investigations which we have carried out using the technique of gel-filtration in both the preparation and analysis of wine tannins. By means of this technique we were able to investigate for the first time their chemical constitution.

The adsorptive capacity of 'Sephadex *G*-25' dextran-gels for wine tannins is almost completely eliminated by preparation of the gel in aqueous alcoholic media. The gel then functions as a molecular sieve for tannins when irrigated with the same aqueous alcoholic solvent, and enables separation of the high polymers in a narrow band. The procedure is rapid and gives quantitative recovery of extract. It has been applied on a preparative scale to the isolation of condensed tannins from dry red table wines. Residual anthocyanins present in the wine are also partially resolved, apparently by adsorptive partition.

Optimal separations were obtained in a medium con[illegible] of 60 parts ethanolic 0·1 per cent hydrochloric [illegible]ated hydrochloric to 1 l. ethanol) and a *p*H of about 2·0. Aqueous meth[illegible] of the same composition serves [illegible]t critical but, as all fractions [illegible]e colour was dependent on [illegible]

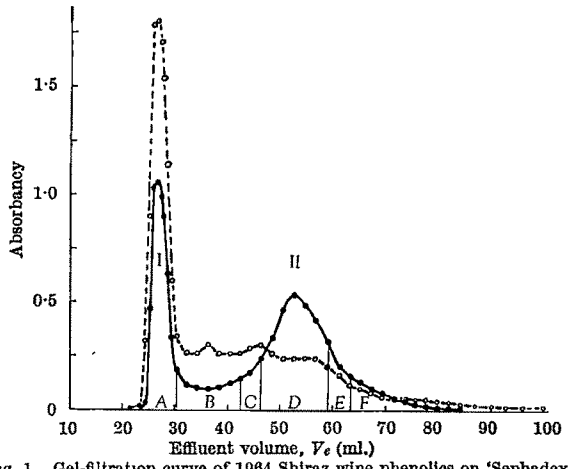

Fig. 1. Gel-filtration curve of 1964 Shiraz wine phenolics on 'Sephadex G-25' in 60 per cent aqueous alcohol (hydrochoric acid). Visible colour. —●—●—, absorbancy at 535–540 mμ (twenty-fold dilution); —○—○—, absorbancy at 278 mμ (fifty-fold dilution)

aforementioned solvent—a glass paper disk was used to prevent disturbance of the gel surface. Non-phenolic wine constituents were first removed from a 1964 dry red wine (*V. vinifera*, cv. Shiraz, 20 ml.) and the phenolics concentrated twenty-fold by precipitation of total phenols with basic lead acetate solution, regeneration and solution in the solvent (1·0 ml.), keeping temperatures below 35° C. The concentrate was applied to the column and the flow-rate adjusted to about 12 ml./h. The pigment quickly separated into two bands, the first (I, very dark red) being completely excluded from the gel ($K_d \neq 0$) and the second (II, bright red) becoming more diffuse with development, adsorption effects being finally evident ($K_d > 1$). Optical densities at the visible maxima (535–540 mμ) and 278 mμ were read after suitable dilution in the same solvent, and plotted against effluent volume, V_e (Fig. 1).

The nature of bands I and II was revealed by paper chromatography of all fractions in *n*-butanol–acetic acid–water (4 : 1 : 5, upper phase). Band I fractions *A* (Fig. 1), dark red in solution, were almost completely immobile, showing as brown stains at the origin with slight brown trailing to about R_F 0·5. Subsequent fractions *B* contained tannins of relatively greater mobility, and anthocyanins (Band II) of progressively decreasing R_F appeared from this point onwards. However, slight quantities of tannin, judged by chromatographic behaviour, still persisted through all fractions to V_e 80 ml. Recovery of total phenolic material was almost 100 per cent within 60 ml. of effluent, and overnight elution with the same solvent gave effluent of zero absorption at 278 mμ. Such columns have been used repeatedly for fractionation of wine pigments in this way.

By co-chromatography with anthocyanins previously identified in Shiraz grape pigment[6], the fractions *D* were shown to contain malvidin 3-glucoside with some petunidin 3-glucoside, the peak fraction having only the former; the content of fractions *E* was similar but with relatively more of the petunidin pigment, and the final eluates from V_e 63 ml. (*F*) contained petunidin 3-glucoside and delphinidin 3-glucoside. The early eluates of Band II, fractions *C*, contained unidentified anthocyanins, probably peonidin 3-glucoside with traces of acylated anthocyanins.

By precipitation with dry ether from solution in ethanol, the condensed tannins of Band I (*A*) were recovered quantitatively as a stable mauve red powder (14 mg), representing, with allowance for that used on optical density measurements, 900 mg/l. in this 1964 wine. The material precipitated gelatin from solution, and the tannin solution in 12 per cent v/v aqueous alcohol saturated with potassium bitartrate had both flavour and astringency.

Gel filtration on 'Sephadex G-25', modified for the polyphenols by use of aqueous alcohol, thus provides a solution to the problem of separate measurement and isolation of wine tannins. An elution curve of total phenols, as in Fig. 1, gives both qualitative and quantitative information regarding the polymerization state of these compounds, as the area under the peaks is a direct measure of contribution to colour at the visible maximum by condensed tannins and monomeric anthocyanins at this *p*H. The content of individual anthocyanins may also be estimated fairly accurately by use of control paper chromatograms.

The ultra-violet absorption of the condensed tannin fraction (Band I, Fig. 1) paralleled the visible absorption, and no phenolic material was eluted which was not highly coloured. The intensely red colour of the tannin band and the fact that the colour is dependent on *p*H suggested that anthocyanidin or anthocyanin pigments are incorporated in the tannin structure. This is quite contrary to present-day theories on wine tannins, which are supposed to be yellow-brown in colour rather like some wood tannins and similarly constituted, principally of leuco-anthocyanidin units[7]. Thus the red colour of wine has been attributed to the monomeric anthocyanin pigments only, with superimposed tannin effects producing the familiar brick-red tints of an aged wine. However, degradative and other data described below have shown that the tannins of red wines actually contain anthocyanin units in their structure, and must be regarded as condensed flavonoid pigments. The changing hues and tints of a red wine are then explicable in terms of the relative contributions of polymeric and monomeric pigments to total colour.

For experimental purposes 160 mg of wine tannin was used. This had been isolated as before by gel-filtration from a 1959 Shiraz red wine (200 ml.), in which the anthocyanin contribution to total colour (Band II) was quite low. The solution of this tannin in 12 per cent v/v aqueous alcohol saturated with potassium bitartrate (*p*H 3·8) had, like that of the 1964 wine tannin, a similar appearance and absorption spectrum to that of an aged red wine, with a maximum at 520 mμ and high absorbance in the 400–500-mμ region (Fig. 2)—an $E^{1\%}_{1\,cm}$ value of 25 was found for the 'simulated' wine solution using this tannin sample. The effect of *p*H on visible colour (Fig. 2), while much less marked than with anthocyanins, was similar to that which characterizes the anthocyanins, through the *p*H range 2–10. At lower *p*H the material was partially precipitated from aqueous or dilute alcoholic solutions.

Micro-analysis of the 1959 tannin gave the following percentages: C 55·4, H 4·7, O 36·5, alkoxyl (as OCH_3) 3·8, N < 0·5. A single extraction with *iso*-amyl alcohol of the products of mild acid hydrolysis removed all pigment

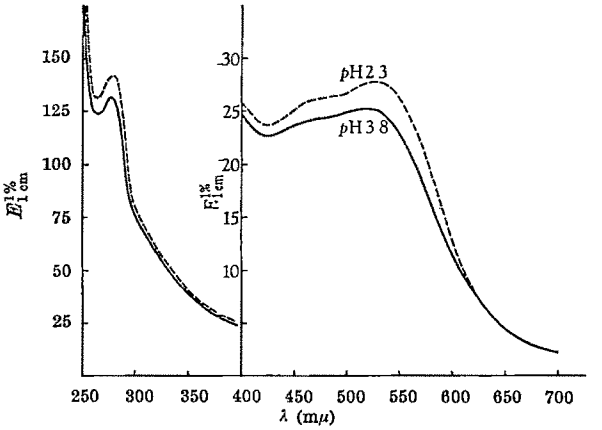

Fig. 2. Absorption spectrum of 1959 Shiraz wine tannin: ———, in 12 per cent v/v aqueous alcohol saturated with potassium bitartrate (*p*H 3·8), – – – –, in 12 per cent v/v aqueous alcohol citric phosphate buffer (*p*H 2·3)

from the reaction mixture, and chromatography of this extract in Forestal solvent or in formic acid–conc. hydrochloric acid–water (5 : 2 : 3) gave three anthocyanidin bands as obtained from Shiraz grape pigment. Multiple chromatography in *n*-butanol–2 N hydrochloric acid (1 : 1, upper layer) of eluted bands enabled identification, by co-chromatography with authentic pigments, of all of the anthocyanidins which occur as their 3-glucosides in Shiraz grapes[6], namely, delphinidin, petunidin, malvidin and peonidin. However, the major anthocyanidin found was cyanidin, derived from the high leuco-anthocyanidin content of the tannin. The aqueous fraction from the acid hydrolysis reaction contained glucose which, analysed by the method of Pridham[8], was found to constitute about 8 per cent of this wine tannin.

The content of 'hydrolysable tannins' in wine is known to be very low[9], so that wine tannins are regarded as 'condensed tannins', and the glucose found present must be still in its original state of combination with anthocyanidins. It is thus evident that the anthocyanin pigments of a new wine, which are known to disappear very rapidly during maturation and ageing, are actually incorporated into the polymeric complex of leuco-anthocyanidin and possibly other flavonoid units. A measure of the extent of this reaction is given by the gel-filtration elution curve, as in Fig. 1. The glucose and methoxyl contents of the wine tannin, together with the relative yield of cyanidin from acid hydrolysis, suggest a ratio of one anthocyanin molecule to about four leuco-anthocyanin moieties in the polymer.

That the mean molecular weight of the wine tannin is comparable with that of other condensed tannins was indicated by application of the concept of Goldstein and Swain[3]. Thus, analysis by the vanillin (V) and Folin Denis (F.D.) reagents for phenols, using catechin as standard, gave $E^{1\%}_{1\,cm}$ values of 116 and 531 respectively. The value of 22 for the ratio V/F.D. per cent, which they showed to be a measure of polymerization, is actually lower than any quoted by these workers for various plant tannins and catechin polymers, indicating a somewhat higher average molecular weight for the wine tannin. The use of the V/F.D. per cent concept is valid in this case as simple phenols, which otherwise give rise to meaningless results[3], have been removed by the gel-filtration procedure.

However, the characteristics of 'Sephadex' gels, once established for condensed polyphenols, may enable the assignment to tannins of accurate molecular weight ranges, as has been done with proteins[10]. In the absence of known standards, it is considered that, since 'Sephadex *G*-25', in the 60 per cent aqueous alcoholic solvent used, swells to about half its volume in aqueous medium, the minimum molecular weight for complete exclusion from the gel, as found with the wine tannins, would be about 2,000. Evidence that a wide range of molecular weights occurs in wine tannins and some idea of the relative distribution throughout this range were obtained by further gel-filtration of the 1959 tannin and of total wine phenols on 'Sephadex *G*-50' and '*G*-100' gels in 40 per cent and 33 per cent aqueous alcohol (hydrochloric acid) respectively. Both gels swelled to about half the normal aqueous value in these solvents. Neither separated tannins from anthocyanins but each gave a wide spread of tannin pigment up to the exclusion point, though no bands were observed. Recovery of tannin from each experiment was quantitative and again no phenolic material was eluted which was not pigmented. Use of '*G*-50' in 60 per cent aqueous alcohol (hydrochloric acid), in which the gel swells to one-quarter the aqueous value, gave complete exclusion of tannin as a narrow band and just separated tannins from smaller pigments in the total phenol extract, showing how the same gel may be modified to give different performances as a molecular sieve for tannins. From these observations it is concluded that most of the condensed polyphenols in this 1959 wine tannin were in the molecular weight range 2,000–5,000, but that some material having molecular weights up to 50,000 was present.

Tannin formation in wines probably proceeds initially by acid catalysed polymerization of leuco-anthocyanidins which are very acid sensitive, but no information is available on the mode of cross-linkage in such poly-leuco-anthocyanins[11]. The finding of anthocyanins in the wine tannin structure poses further problems—so far as we are aware, no 'polymeric anthocyanins' have previously been reported. The ease with which anthocyanidin pigments are released from the tannin structure by mild acid hydrolysis suggests that only weak chemical bands are involved between the main leuco-anthocyanidin matrix and anthocyanins, if indeed any at all. It does, in fact, seem reasonable to postulate that the pigment molecules are physically rather than chemically incorporated into the three-dimensional tannin structure of C_{15} leuco-anthocyanidin units. Between five and fifteen flavonoid units are apparently involved in the tannin structure, and physical inclusion in a coiled structure is a possible explanation of the development of tannin pigments in an ageing wine.

Although condensed tannins from different sources are of diverse chemical types, it seems likely that any extract of plant phenolics could be handled by gel-filtration in the manner described for wine phenolics, and the condensed tannin fractions thus isolated. Lignin degradation products of suitable solubility might also be purified in this way. Finally, the adsorptive effect observed with the anthocyanins suggests that 'Sephadex'-gel columns could be useful for preparative partition chromatography of these pigments.

VARIATIONS IN AMINO-ACID SEQUENCE NEAR THE DISULPHIDE BRIDGES OF BENCE-JONES PROTEINS

By Dr. C. MILSTEIN

Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge

ONE of the key problems in investigations of the molecular basis of the immune response is the mechanism by which an indefinite number of protein molecules are synthesized to account for the large number of highly specific antibody activities. In spite of their functional heterogeneity, a surprising structural similarity of the antibody molecules is observed. This similarity is well illustrated by the common arrangement of two pairs

of chains—$A(H)$ and $B(L)$ chains—proposed for all 7S antibodies[1,2]. However, a high degree of heterogeneity has been shown on isolated L chains[3,4], and has also been suggested on isolated H chains[5]. It is now generally believed that this heterogeneity is the result of the functional heterogeneity already referred to. What appear to be single molecular species of chains have been isolated from myeloma proteins, which do not share the heterogeneity, possibly because they derive from a single clone of tumour cells[6]. The observation that the Bence-Jones proteins of myeloma patients represent in most cases isolated L chains[7,8] has helped considerably in a more detailed chemical investigation of the nature of the heterogeneity. So far two immunologically distinct types of Bence-Jones proteins have been established[9,10] and named, type K (I) and type L (II). Each of these has a characteristic C-terminal sequence, and studies of the yield of these sequences have indicated that most of or all the heterogeneous population of normal L chains contains them in the same proportions[11] as the proportion of type K and type L reacting material observed in normal serum[9,10]. Recent work has shown the sequences of two individual Bence-Jones proteins to be similar along a stretch near the C-terminus of the chain. With the exception of a single residue, identical peptides accounted for half the total protein, and overlapping of the peptides located them at the C-terminal half. The peptides of the other half showed no clear similarities[12]. Analysis of a third Bence-Jones protein indicated in some detail that the sequence in the C-terminal half of the chain was the same as in the other two, with the exception of the single residue already mentioned. However, in this case the N-terminal peptide, which comprises eighteen residues, was probably also identical with that of one of the two other proteins[13]. There is an obvious need for analysing a larger number of proteins, which is difficult, but a wider survey of selected stretches of chain, such as those adjacent to the disulphide bridges, may give useful information.

Two disulphide bridges may be common to many or all individual type K Bence-Jones proteins[14]. The corresponding sequences have also been found in the three Bence-Jones proteins already mentioned, suggesting that the common C-terminal half is folded so as to link cysteines in positions 192 and 132. (Numbering of residues throughout is taken from ref. 12.) The C-terminal cysteine provides the interchain link[13]. Another two cysteine residues have been observed in at least six proteins—the protein of Roy[12] and five individual Bence-Jones proteins in which the cysteine peptides were investigated (see later). These two cysteine residues were bridged to form the third disulphide in the protein B.J.[13]. It remains to be seen if all proteins of the K type have five cysteine residues linked in two intra-chain and one inter-chain bridge, or whether there are exceptions to this rule.

The variation of the sequence of the L chains has now been investigated with the help of a radioactive technique. The disulphide bridges of Bence-Jones proteins were quantitatively reduced and alkylated with ^{14}C-iodoacetate; the radioactive protein was then digested with trypsin or chymotrypsin, and the radioactive peptides purified by 'Sephadex' fractionation and paper electrophoresis. This technique is suitable for the analysis of longer stretches of sequences in a comparatively large number of proteins. I shall discuss the results obtained in a preliminary study of five of these proteins and compare them with the information obtained from other proteins.

The C-terminal stretch. Cysteines in positions 212 and 192 have facilitated the analysis of the last twenty-four amino-acid residues of the five proteins. The results summarized in Table 1 support the conclusion that in the eight proteins listed the only variation is that at position 189, where either Val or Leu is found. So far Leu has always been associated with the Inv factor (a) and Val with Inv (b). The detailed evidence for the new sequences reported here will be published elsewhere. The order of the residues in parenthesis has been decided only on comparative grounds. The next cysteine residue going towards the N-terminus has provided evidence for the similarity in a stretch comprising residues 112–133; that is, a stretch of 22 residues just after the first half of the molecule. The results listed in Table 2 show no detectable difference.

The 'variable' region. The peptides containing the two cysteine residues which occur next in protein Roy (going towards the N-terminus) can be identified in several Bence-Jones proteins from their amino-acid analysis and partial sequences. Table 3 shows a comparison of the sequences around the cysteine which, on the basis of these results, is probably residue No. 86. There are some interesting differences, some of them based on established sequences and others based only on amino-acid analysis and comparison with the established sequences. In

The corresponding peptides from the proteins of Day and Man have not been prepared.

several cases the peptides are extremely similar. A reasonable guess about the sequence of a variable peptide of which only the amino-acid composition is known seems to be possible, and this in itself is a very interesting observation. Table 4 shows the comparative sequences around the cysteine residue, which is probably No. 23 (Roy numbering). Again great similarities are observed, but there are also well-established differences in some residues. Investigations of disulphide bridges have been carried out on three of these proteins (B.J., Rad, and Ker). The results indicate that the two variable cysteine residues form a disulphide bridge.

The detailed analysis of the variable region is particularly interesting because it makes it possible to test hypothetical mechanisms by which variability in protein sequences could be achieved starting from a much simpler set of genes. There are several assumptions one is forced to make for such a test, the most important being that the proposed genetic code[15] is applicable to the system under investigation.

The simplest question one can ask is the following: Is it possible to explain all the differences by using only two different sets of nucleic acid sequences with multiple crossing-over and strict preservation of phase? Let us assume, as an example, the following two sequences of nucleotides:

(1) GAA ACG UCU
(2) CUU GAU CUU

Sequence (1) may code for—Glu.Thr.Ser.
Sequence (2) may code for—Leu.Asp.Leu.

Sequence (1) corresponds to the sequence of Rad 90–92 (see Table 3). All variations found in those three positions of Table 3 can be explained by interchanging nucleotides of these two sequences as follows:

GAU GAU CUU (crossing at second base)
Asp.Asp.Leu as Ker
GAA AAU CUU (crossing at fourth base)
Glu.Asn.Leu as B.J.

The only other established position in this region is Cu 90 which is a Leu, which is also in agreement with the nucleotide sequence (2). Unfortunately, this hypothesis does not explain the three residues at position 94 (Thr, Pro and Tyr) which require as first code letter A, C and U. The position is worse if either Leu or Phe is confirmed in position 94, if Gly is confirmed at position 98, and if either Phe or Leu is confirmed at position 89 (all in Roy protein).

The variations observed in Tables 3 and 4 do not seem to fit with the intra-chromatid inversion hypothesis[16]. A direct test can be made if only one inverted loop is allowed. The model predicts in that case that there should not be two variant regions separated by a common stretch. Protein B.J. and Rad (Table 3) have a region of variation between positions 90 and 94 and the five residues preceding it are identical. Yet the peptide with cysteine in position 23 of B.J. was not found in Rad, but a completely different peptide around a cysteine residue was found instead, indicating that at least two variable regions were separated by a common stretch which involves not less than five residues. Other examples of this sort may be inferred from the available data.

Another hypothesis which has been tested is the one proposed by Potter, Appella and Geisser[17]. According to this hypothesis, some unusual triplets coding only for the variable region will bind specific *s*RNA charged with amino-acids which will differ from clone to clone due to specificity changes of the activating enzymes. This would suggest that replacements of a given residue in a new sequence should be done with only one amino-acid. That is, the *s*RNA involved in, say, two sites containing aspartic acid, instead of being charged with Asp in a different clone will be charged with some other residue; it would then be likely that both sites will contain the same residue, whichever it may be. In Table 3 protein Ker shows Asp in positions 90 and 91 and the corresponding residues in B.J. and in Rad are Glu. Asn and Glu. Thr, respectively.

Investigations of the sequences around the cysteine residues of several individual Bence-Jones proteins, combined with previous sequence studies, indicate that the heterogeneity of the *L* chains of γ-globulin is the result of the heterogeneity of restricted stretches of the polypeptide chain. So far, and with the exception of a Val/Leu substitution, which seems to be related to the Inv factors, no variation in the C-terminal half of the molecule has been found. This half includes one common intra-chain disulphide bridge and the inter-chain disulphide bridge. Possibly the invariance of this region is due to the strict requirements for inter-chain binding, essential to the

The position of the residues in parenthesis is suggested by comparison with the other specimens. When there were no grounds for comparison the residues were placed in random order and underlined. From Day's protein a peptide was isolated with an amino-acid composition, His,Cys,Thr,Ser,Glu,Ala,Phe. This is presumed to be a large variation of the sequence around the corresponding half cystine. Similarly the protein from Man gave two Cys peptides which could not be related to either the common sequences of this Table or those of Table 4.

formation of the complete antibody, and perhaps other common—but so far unestablished—functions.

The variations of the other half of the molecule present varying characteristics. Some proteins may be very similar indeed. In those cases (as Ker, B.J., Roy and Ag) all that has been observed so far are variations of individual residues, which may include stretches of a small number of residues. In other examples much larger variations around a cysteine residue are found, which may reflect very large variations in a given stretch. Some attempts have been made to see whether these sequences could be related by phase shifts and/or inversions, but without success. We cannot exclude the possibility of some cysteine residues being located differently in individual Bence-Jones proteins, and this is in fact suggested by the available data on Cummings's protein[12].

Several simple hypotheses which could explain the variability of certain regions of the protein starting from a small number of parent genes have been tested but none of them accounts for all the variations observed. If further assumptions are made, such as, for example, the operation of more than one of these hypothetical mechanisms, it becomes progressively more difficult to exclude them on the sole grounds of comparative sequences.

I thank the members of the Laboratory of Molecular Biology, Cambridge, for many helpful suggestions, and Mr. J. Jarvis for his skilful technical assistance.

SPECIFICITY AND PREVENTION OF ANTIBIOTIC RESISTANCE IN *Staphylococcus aureus*

By SAMUEL J. De COURCY, jun., and Prof. M. G. SEVAG

Department of Clinical Pathology, Philadelphia General Hospital and Department of Microbiology, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

In previous communications[1–6] it was reported that the emergence of antibiotic resistance in *Staphylococcus aureus* and *Escherichia coli* is prevented by incorporating into the medium the combination of an antibiotic, to which the organisms have never previously been exposed, together with atabrine or spermine. It must be noted that, conversely, prior exposure to an antibiotic enabled these organisms to grow in the presence of the homologous antibiotic–atabrine combination. Thus, it is possible to differentiate the *de facto* antibiotic-resistant bacteria from those which have the potentiality but fail to give rise to demonstrable resistance. Streptomycin resistance can develop in penicillin-resistant staphylococci following their exposure to streptomycin, but our experimental results show that this resistance failed to appear when the penicillin-resistant organisms were exposed to the combination of atabrine plus streptomycin. We decided to carry out a more comprehensive investigation in order to determine whether or not these findings applied to other antibiotics of diverse chemical structure and mechanism of action.

To evaluate our results on a comparative basis, the inocula in a prototype experiment were prepared from single clones and replicated according to the Lederberg technique[7], on antibiotic-free and corresponding antibiotic-supplemented agar plates. It was necessary to determine the optimal concentration of antibiotic in these plates by prior titration. Under the conditions used, the same number of colonies grew in both antibiotic-free and antibiotic-supplemented replica agar plates.

The sister colonies obtained by this method were individually suspended in M/30 phosphate buffer, *p*H 7·35, and used as the inocula into growth systems. All the growth systems contained the same liquid medium (see footnote to Table 1) and included the specific antibiotic in the presence of which the colony had grown on an agar plate. At the same time, similar growth systems, each containing other individual antibiotics, with and without atabrine, were inoculated with the same number of cells from the corresponding bacterial suspensions of replicated colonies. In this report only the results with streptomycin and erythromycin are presented; these are considered to be representative of the results which we obtained.

The data presented in Tables 1 and 2 reveal that, whereas the clone exposed to a given antibiotic can survive the combination of that antibiotic plus atabrine, the same clone is incapable of surviving the combination of other antibiotics plus atabrine. This would seem to emphasize the fact that each drug elicits the development of specific resistance.

The results presented in Table 3 are from a systematic investigation undertaken to determine the stability of drugs incubated for a prolonged period in a sterile medium. This was made necessary by the fact that aureomycin deviated from the common pattern of results (see under "Freshly prepared systems", Table 3) by growth during a period of 221 h. It can be seen that the potency of aureomycin, on incubation in a sterile medium, with or without atabrine, decreases, and thus this antibiotic was found to be incapable of preventing the emergence of even normal strains. It can also be seen that, with the exception of chloromycetin, all other drugs deteriorate to varying extents (see the results given under "Aged systems", Table 3). It should be emphasized, therefore, that reliable conclusions can be made from results observed in experiments with antibiotics plus atabrine, which are confined to a short period of time (that is, 48–96 h) during which a complete bactericidal action must occur. The results presented in Table 4 show that the two different clones, when exposed to streptomycin and 'Novobiocin', respectively, may reveal differences as regards their ability to survive in 150 μg of streptomycin alone (compare system *A*-3 with system *C*-3, Table 4). Furthermore, the clone exposed to streptomycin and later grown in 'Novobiocin' plus atabrine (system *B*-6), and the clone exposed to 1·5 μg of 'Novobiocin' and later inoculated into 5 μg of 'Novobiocin' plus atabrine (system *D*-6), failed to produce a 'Novobiocin'-resistant strain, thus indicating the possible need for added exposures to acquire a capacity for survival in 5 μg of 'Novobiocin'.

Bacteria inoculated into series of identical growth systems, which individually contain various antibacterial agents, multiply following a period of suppression of division, or following the elimination of certain numbers of bacteria by death, or when both actions occur simultaneously. Those which can survive the drug action and multiply are considered to be drug-resistant. Bacteria that are already resistant to one drug but can also multiply in the presence of unrelated drugs are considered to possess cross-resistance. These facts have been explained by the supposition that a normal population of bacteria contains pre-existent drug-resistant individuals which survive the drug-action and multiply. Since strains capable of surviving various other drugs can emerge from a given normal population, it has been surmised that the normal population may contain as many pre-existent drug-resistant individuals as there are drugs. On this basis, one could postulate that a normal population of bacteria should manifest a cross-resistance behaviour.

The concept outlined here has derived additional support from the results of experiments by Lederberg, using a replicating procedure. Originating from a single clone or a 'master' colony, the growth of replicated colonies on geometrically superimposable loci in drug-supplemented plates has been interpreted to show that the corresponding sister colonies on drug-free plates, and the master colony as well, possess the same drug-resistant character as that which grows on the drug-supplemented agar plate. In other words, the master colony and the sister colony on the drug-free plate are interpreted to be resistant without prior exposure to the drug used.

In reality, however, and despite the refined procedure used by Lederberg, the fundamental question remains unanswered of whether or not the cells in the parent colony and the sister colonies derived therefrom (with and without drug) are in all cases resistant to start with, or prior to multiplication in the presence of drug. To answer this question, a more sensitive procedure was required which made allowances for the differentiation of the actually resistant bacteria and those which were disposed to, or possess the potentiality for, the acquisition of a resistance character triggered by drug action. In addition, it was most important to set up a critical growth system which made allowances for the free growth of bacteria with

established resistance character, but which at the same time eliminated, by death, those which possessed potential, but not actual, resistance. Such requirements for the absolute characterization of these two types of bacteria were met by the findings[2,3] that a strain of bacteria which has been exposed only once to a given drug can readily grow in a combination of that drug plus spermine or atabrine. In contrast, the strain of bacteria which has never before been exposed to that drug is completely eliminated by death under identical conditions. Furthermore, the specificity of these reactions, or the absence of a cross-resistance character in a bacterium resistant to a single drug, was demonstrated by the finding that, where penicillin-resistant staphylococci can survive the action of streptomycin *per se*—giving the appearance of the presence of a cross-resistance character—the same penicillin-resistant strain is annihilated in a combination of streptomycin plus spermine or atabrine. This shows the absence of streptomycin-resistance character in the penicillin-resistant strain, and that the survival in the absence of spermine or atabrine is due to an acquisition of a secondary resistance to streptomycin.

Expanding the foregoing findings in the present study, replicated colonies grown both in the presence and absence of an antibiotic were subjected to a systematic investigation to elucidate, in a broad sense, the question of the specificity of resistance to a drug and of cross-resistance to other drugs (such as streptomycin, tetracycline, penicillin, erythromycin, chloromycetin, 'Novobiocin' and aureomycin). For example, the sister colonies which were grown with, and without, streptomycin were challenged by the afore-named antibiotics with and without atabrine.

The findings from all freshly prepared systems, as presented in Tables 1, 2 and 4, clearly show that each antibiotic produces a certain degree of its own specific effect of resistance. In other words, the colonies grown in the presence of a given antibiotic are capable of surviving a combination of that antibiotic plus atabrine, but are incapable of surviving similar combinations with other antibiotics.

In conclusion, we believe that our previous findings[1-6,8-17] and those presented here differentiate the resistance character established in bacteria following exposure to a drug from those of a potential nature. It would seem that the commonly supposed selection of resistant individuals in a bacterial population deals primarily with the selection of those bacteria which possess the potentiality for resistance. This potentiality is specifically triggered into an actual resistance by a

drug, but is blocked by a combination of any number of antibiotics plus atabrine or structurally related phenothiazine tranquillizers or antidepressants[6]. Conversely, the pre-existent drug-specific resistance character would seem to be insusceptible to this blockage.

We thank Dr. Stuart Mudd for his advice during the course of this work, which was aided by a contract between the Office of Naval Research, U.S. Department of the Navy, and the University of Pennsylvania; the National Institutes of Health, U.S. Public Health Service, grant A1–05473, and U.S. Veterans Administration Central Office Research Service.

FUNCTIONAL SITES IN TRANSFER RIBONUCLEIC ACID

By HIROSHI HAYASHI and Dr. KIN-ICHIRO MIURA
Institute of Molecular Biology, Faculty of Science, Nagoya University, Chikusa, Nagoya, Japan

ACCORDING to present concepts of protein biosynthesis[1,2] the raw materials of a protein molecule, amino-acids, are arranged on a template by transfer ribonucleic acids (*t*RNAs). Each *t*RNA molecule, which is specific for each of the twenty common amino-acids, combines with a definite amino-acid with the aid of a specific aminoacyl RNA synthetase. An aminoacyl RNA thus synthesized is transferred by a common transfer enzyme on to a definite position on the messenger RNA (*m*RNA). The *m*RNA serves as a template for a polypeptide and forms a polysome with a few ribosome particles. A *t*RNA molecule selects the correct position among nucleotide sequences of the *m*RNA by virtue of its adaptor site (or coding site), which is considered to be a complementary sequence to the codeword of the *m*RNA. However, little is known about the sites of specific interaction between *t*RNA molecules and aminoacyl RNA synthetases. A *t*RNA molecule must 'recognize' a specific aminoacyl RNA synthetase in order to pick up a specific amino-acid from the amino-acid reservoir. In order to determine the site in *t*RNA which 'recognizes' the aminoacyl RNA synthetase, an investigation was undertaken of the inhibitory effect of various kinds of polynucleotides on the aminoacylation of *t*RNA[3]. It was assumed that inhibition would be observed when the polynucleotide contained a specific structure corresponding to the site in *t*RNA which 'recognized' the aminoacyl RNA synthetase.

Modified *t*RNA, which was oxidized by periodate to destroy the acceptability of amino-acid, inhibited the aminoacyl RNA synthetase. Similar results have already been reported by other research workers[4,5]. Ribosomal RNA showed no inhibitory effect, but the ribosomal RNA partially degraded by mild alkaline treatment had an inhibitory effect. A mild alkaline digest of *t*RNA was also found to be inhibitory. The inhibition by these poly- (or oligo-) nucleotides was competitive with the aminoacylation of *t*RNA, and this did not depend on the terminal phosphate of the oligonucleotide. For valine incorporation into *t*RNA, oligonucleotides longer than tetranucleotides in the ribonuclease digest of RNA showed an inhibitory effect, whereas dinucleotides showed no effect and trinucleotides showed little effect. This article reports on the inhibitory effect of several kinds of synthetic oligonucleotides on the incorporation of amino-acid into *t*RNA, and discusses a possible structure for the site in *t*RNA responsible for 'recognizing' the aminoacyl RNA synthetase.

Aminoacyl RNA synthetase, which was partially purified from brewer's yeast, was incubated with *Torula* yeast *t*RNA, amino-acids and other requirements. (Details of the reaction mixture were given in an earlier report[3].) The amino-acid to be tested was labelled with carbon-14 and added to a mixture containing the other nineteen unlabelled amino-acids. The incubation was carried out at 37° C. At various times the radioactivity incorporated into the nucleotide (insoluble in 5 per cent cold trichloroacetic acid (TCA)) was counted. The polypeptide was insoluble both in cold TCA and in hot TCA, whereas aminoacyl *t*RNA was soluble in hot TCA. In this experiment there was a small, but negligible, radioactivity in the hot TCA insoluble fraction of the reaction product. Therefore, it would seem that amino-acids were only incorporated into *t*RNA. The incorporation of amino-acid into *t*RNA increased linearly during the initial 10 min of the reaction. We measured the incorporation 3 min after the commencement of incubation. It was felt that this might give an indication of the initial rate of the reaction. In order to observe an inhibitory effect for this reaction, oligonucleotide was added to the reaction mixture at various concentrations. The oligonucleotides were synthesized chemically according to Michelson[6].

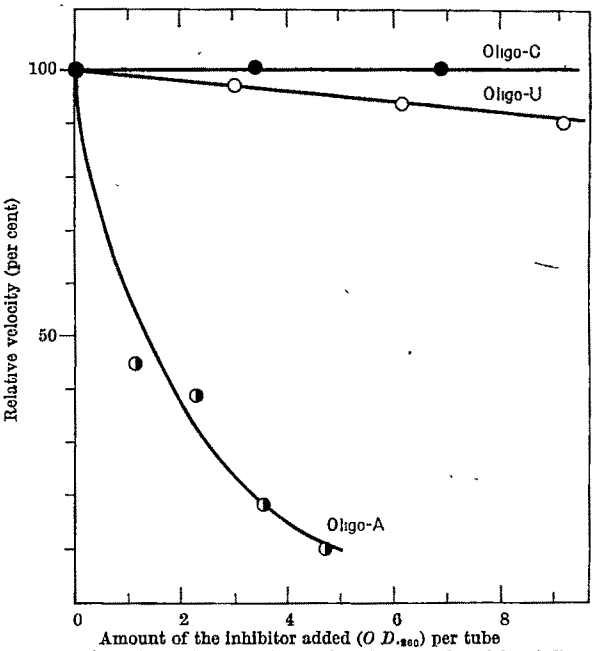

Fig. 1. Inhibitory effect of oligonucleotides for phenylalanyl RNA synthetase. Reaction medium contains: 6 μmoles of ATP, 60 mμmoles of 19 amino-acids, 60 mμmoles of ^{14}C-phenylalanine (10⁶ c.p.m.), 50 μg of partially purified aminoacyl RNA synthetase, 12 mμmoles of transfer RNA, and various amounts of inhibitor in 0·6 ml. of 0·01 M Mg^{++}–0·05 M *tris* buffer, *p*H 7·5. Incubation at 37° C for 3 min gives an initial velocity

(Oligonucleotide samples were gifts from Dr. A. M. Michelson, whom we thank.) The average chain-lengths (estimated by terminal and total phosphate analysis[7]) of oligouridylic acid (oligo-U), oligoadenylic acid (oligo-A), oligocytidylic acid (oligo-C), and oligoguanylic acid (olgio-G) were 4·8, 5·6, 5·2 and 5·6, respectively. These synthetic polymers contained 2′-,5′-phosphodiester linkages as well as 3′-,5′- phosphodiester bonds. A mild alkaline digest of poly-A synthesized by polynucleotide phosphorylase from *Micrococcus lysodeikticus*[8] was also used. The free phosphate ends of these oligonucleotides were eliminated by *Escherichia coli* phosphomonoesterase[9].

The rate of the formation of phenylalanyl *t*RNA was strongly inhibited by the addition of oligo-A, but only slightly by oligo-U, while oligo-C showed no inhibition (Fig. 1). The inhibition of the phenylalanyl RNA formation by oligo-A was a typical competitive inhibition as seen in the Lineweaver–Burk plots of $1/v$ against $1/s$ for various concentrations of the 'inhibitor' (Fig. 2). The rate of lysine incorporation into *t*RNA was strongly inhibited by oligo-U in a competitive manner, only slightly inhibited by oligo-A, and not inhibited by oligo-C (Fig. 3 and Fig. 4). The incorporation of proline into *t*RNA was inhibited

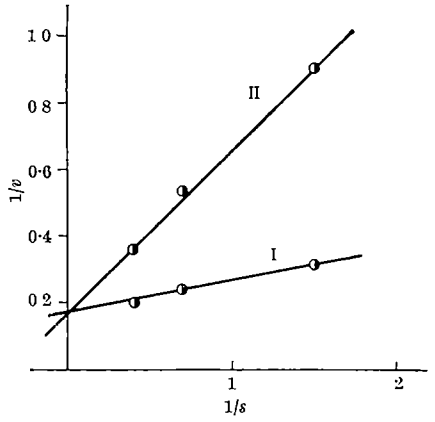

Fig. 2 Competition between *t*RNA and oligo-A for yeast phenylalanyl RNA synthetase. I, Reaction medium contains 10–40 mμmoles of *t*RNA, others are same as Fig. 1, without inhibitor. II, Oligo-A is added as an inhibitor at the concentration of 4·8 *O.D.* units per 0·6 ml. Units of the substrate concentration are μmoles of phenylalanyl *t*RNA/l , and velocity is mμmoles *t*RNA acylated per hour per tube

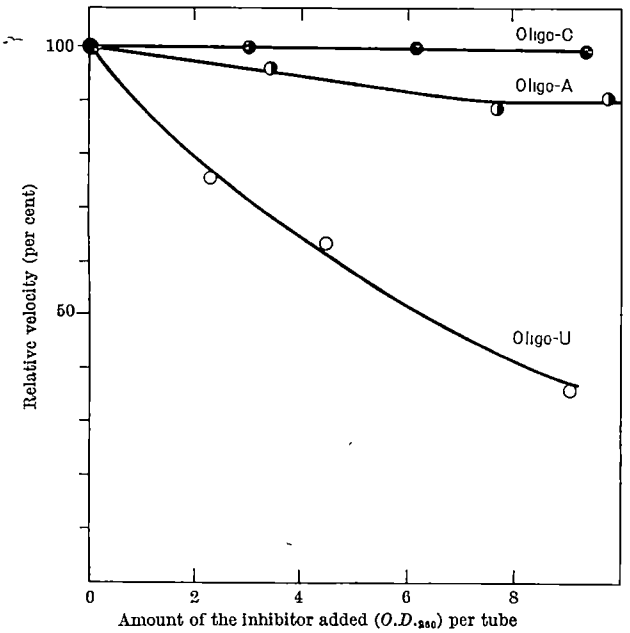

Fig. 3. Inhibition effect of oligonucleotides for lysyl RNA synthetase. Reaction mixture is the same composition to Fig. 1, except ^{14}C-lysine ($1·7 \times 10^4$ c.p.m./mμmole) has been used instead of ^{14}C-phenylalanine

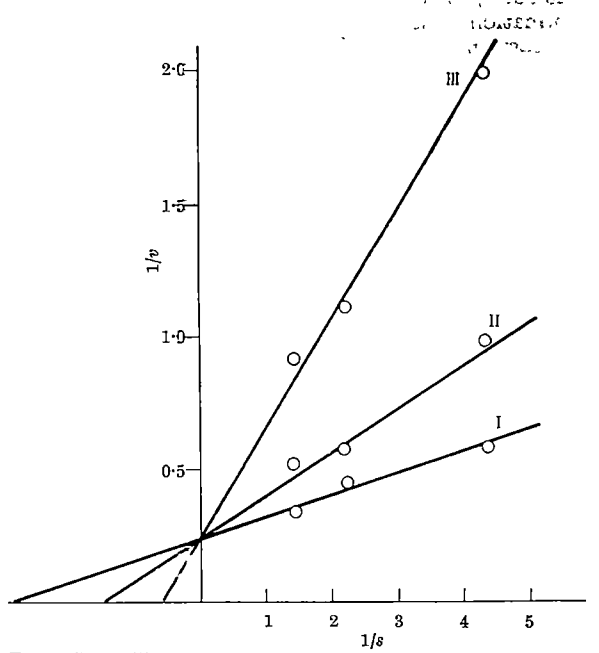

Fig. 4. Competition between *t*RNA and oligo-U for lysyl RNA synthetase. I, without inhibitor. II, Inhibited by oligo-U (4·5 *O.D.* units/0·6 ml.). III, Inhibited by oligo-U (9 0 *O.D.* units/0·6 ml.). (Units of *S* are mμmoles of lysyl *t*RNA per 0·6 ml. Units of *V* are mμmoles of *t*RNA acylated per hour per tube)

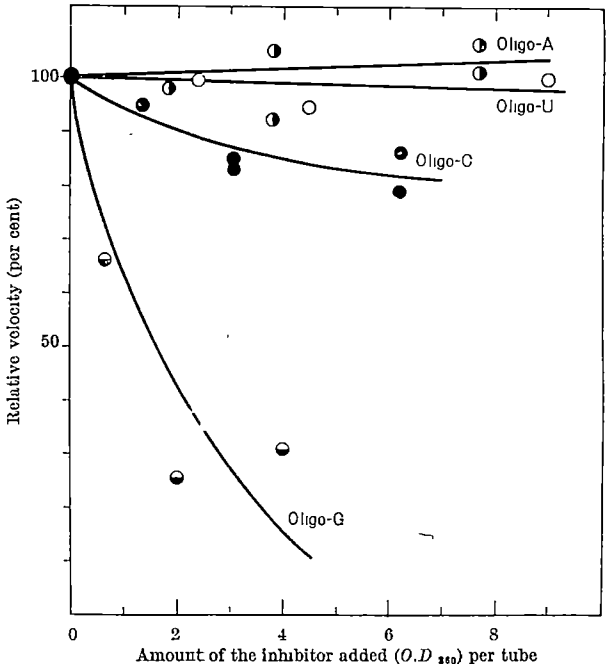

Fig. 5. Inhibition effect of oligonucleotides for prolyl RNA synthetase Reaction mixture is the same composition to Fig. 1, except ^{14}C-proline ($1·7 \times 10^4$ c.p.m./mμmoles) has been used instead of ^{14}C-phenylalanine

strongly by oligo-G, slightly by oligo-C, but not inhibited by either oligo-A or oligo-U (Fig. 5).

If a *t*RNA molecule contains a complementary sequence for a codeword of *m*RNA as suggested in the adaptor concept of Crick[1], phenylalanine RNA may contain ApApAp as a coding site for *m*RNA, since the codeword of *m*RNA for phenylalanine is UpUpUp[10,11]. A reasonable amount of triadenylic acid cluster was observed in unfractionated *t*RNA molecules[12]. The fact that the incorporation of phenylalanine into *t*RNA is inhibited by oligoadenylic acid clusters might be considered as follows: the enzyme recognition site in phenylalanine *t*RNA would also be an adenylic acid cluster. Slight inhibition of phenylalanine incorporation into *t*RNA by oligo-U would be caused by the formation of complementary complexes

for the adenylic acid clusters in *t*RNA. It is possible that the formation of such complexes may reduce the velocity of the reaction. The inhibition by oligo-U to phenylalanine incorporation did not extend beyond 15 per cent with increasing quantities of oligo-U.

For the incorporation of lysine and proline into *t*RNA also, the complementary oligonucleotide to the *m*RNA codeword showed competitive inhibition and the same sort of oligonucleotide as the *m*RNA codeword caused slight inhibition, since the *m*RNA codewords for lysine and proline are ApApAp and CpCpCp, respectively[13,14]. If the anti-codon part (that is, the coding site in *t*RNA) were to consist of complementary nucleotides to the *m*RNA code and the codeword were to be universal for any species, we might assume from the foregoing results that the coding site also (or the same nucleotide sequence as the coding site) acts as an enzyme-recognizing site when a specific amino-acid is incorporated into the terminal site of the specific *t*RNA by the specific aminoacyl RNA synthetase.

Usually a cross-reaction between *t*RNA and amino-acyl RNA synthetase from different sources shows species specificity, which suggests that the enzyme recognizing site in *t*RNA would vary from species to species. Loftfield and Eigner[15], however, found that the Michaelis constants were quite similar for the amino-acylation of *t*RNA by heterologous enzyme when compared with the constants obtained for amino-acylation by the homologous enzyme. They concluded that the enzyme-recognizing site may be identical in all species and that it may be unnecessary to distinguish it from the coding site in *t*RNA. Modification of *t*RNA from different species by bromination led to inactivation of aminoacylation at different rates[16]. Yu and Zamecnik[16] concluded that the enzyme-recognition site in *t*RNA varied from species to species and that it differed from the coding site in the same molecule. Other workers came to similar conclusions after studying the effect of modifications of *t*RNA by treatment with nitrous acid[17], by methylation and bromination[18], or by irradiation with ultra-violet light[19]. These treatments, however, might conceivably inactivate *t*RNA not only by a direct modification of the enzyme-recognition site, but also through changes in the tertiary structure essential for the *t*RNA activity arising from modifications of parts other than the enzyme-recognizing site. Such a phenomenon is suggested by the various inactivation experiments of the aminoacylation of *t*RNA by semicarbazide modification of cytosine residues[20], or by ribonuclease treatment[21]; this possibility is discussed even in those reports which concluded that the enzyme-recognizing site and the coding site were different.

Structural differences in the *t*RNAs specific for an amino-acid among different species have, in fact, been observed[22–24]. If the enzyme-recognizing site were identical throughout all species, the structural differences would be located at sites other than these functional sites.

That the enzyme-recognizing site and the coding site in *t*RNA were identical was also suggested by a few modification experiments. Penniston *et al.*[25] compared the inactivation rates of the aminoacylation activity and of the transfer activity to polysome for the formaldehyde-modified *t*RNA and found that they (the rates) were similar. Zachau[26] modified uracil residues in *t*RNA with ultra-violet light, which makes uracil dimerize intramolecularly. The incorporation of lysine into *t*RNA decreased much more than did phenylalanine. He considered that the anti-codons of lysine *t*RNA and of phenylalanine *t*RNA might be UpUpUp and ApApAp, respectively, and that they might also act as the enzyme-recognition site, so that the ultra-violet inactivation was more effective for the inhibition of lysine incorporation. Similar experimental results[27] were also obtained by a specific modification of uracil residues in *t*RNA with treatment by hydroxylamine at *p*H 9. These data are in agreement with our present results and their interpretation.

QUANTITATION OF PERIPHERAL BLOOD LYMPHOCYTE CULTURES

By A. S. COULSON and Dr. D. G. CHALMERS

Department of Pathology, University of Cambridge

THE tissue culture of human lymphocytes separated from peripheral blood has become widely used to investigate the responses of lymphocytes to antigens *in vitro*. This technique provides a possible method for investigating the immunological status of the lymphocyte donor.

The lymphocytes obtained from human blood are mostly small. If these cells are kept in culture without any apparent stimulus a small number of them spontaneously transform into 'blast' cells (Fig. 2). If the initial population of small lymphocytes is more than 90 per cent pure then after 80–90 h in culture the majority of leucocytes present are lymphocytes or 'blast' cells.

There are many reports that antigens stimulate the transformation of lymphocytes into 'blast' cells *in vitro*[1]. Our experiments with cultures derived from almost pure suspensions of lymphocytes suggest that the lymphocyte is the source of these dividing 'blast' cells. Experiments with lymphocytes from different donors mixed together confirm that in the presence of foreign cells the transformation into 'blast' cells is greatly increased over simultaneous unstimulated control cultures.

The problem is to quantitate this phenomenon of lymphocyte transformation *in vitro* in a meaningful way. Some workers have cited the percentages of blast cells found after a certain period as an indication of the responsiveness of the ... the antigen used *in vitro*. However, using tet... d as the antigen, a number of differing percentages has been found; these are listed in Table 1.

Factors affecting percentage. There are at least three separate events occurring in the cell suspension which have a direct bearing on the final percentage of 'blast' cells. First, part of the original small lymphocyte population may die and disintegrate, if not naturally as a result of manipulation procedures, then by the lethal effect of the antigen on sensitized cells. There are reports of *in vitro* lysis of leucocytes by tuberculin and by a soluble extract from an 8-h *Salmonella enteritidis* broth culture[5,6]. In addition, certain stimulants or the preservatives they contain may be directly toxic to some of the small lymphocytes.

The decline in total cell counts during short-term culture in the presence of tetanus toxoid is shown in Fig. 1. The scatter of the points does not permit a precise determination of the shape of this curve so the best straight line was fitted to the points as a first approximation. Infinite weight was attached to the point at zero time since all experiments had been standardized at the beginning, and a line was drawn through the centre of gravity of the points. The error was estimated by calculating the mean deviation from this best straight line of the y co-ordinates for those points above the line, and for those below.

Secondly, the 'blast' cells are actively dividing in culture. Sampling shows that over a 20-h period in the same culture there is an increase in the absolute number of 'blast' cells per mm³ of culture. This point is illustrated by results in Table 2.

Finally, the 'blast' cells may die and disintegrate. Thus it is more meaningful to refer to the absolute number of 'blast' cells per mm³ in a culture at any given time rather than to the percentage.

Index of response. Accurate quantitation of 'blast' cell production in culture is promoted by allowing cultures only a standard time for growth and development. In particular this time period should be such that the small lymphocytes have sufficient time to transform into large 'blast' cells, but not so long that the 'blast' cells have themselves proliferated by division to any great extent. Once the absolute number of 'blast' cells per mm³ has been determined it is possible to derive an index of response.

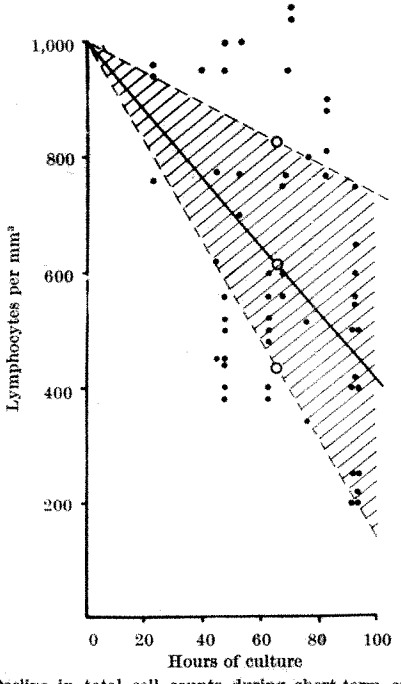

Fig. 1. Decline in total cell counts during short-term culture with tetanus toxoid. The points are readings taken from 25 cultures

Table 1. PERCENTAGES OF 'BLAST' CELLS FOUND IN LYMPHOCYTE CULTURES AFTER TETANUS TOXOID STIMULATION

Investigators	Time of sampling	Percentage
Ling and Husband (ref. 2)	4 days	4
Cowling and Quaglino (ref. 3)	72 h	7
Elves *et al.* (ref. 4)	72 h	> 30

Table 2. INCREASE OF 'BLAST' CELLS IN MIXED LYMPHOCYTE CULTURES WHICH INITIALLY CONTAINED 2,000 ± 90 LYMPHOCYTES PER MM³

Culture reference	Absolute number of 'blast' cells per mm³ At 70 h	At 90 h
EVA/COO	72 ± 4	173 ± 9
LAY/GOU	110 ± 6	297 ± 15

Let T_0 = time when culture starts,
T_s = time of sampling,
N = original absolute number of small lymphocytes per mm³ at T_0,
n = absolute number of 'blast' cells per mm³ present at T_s.

Assuming all 'blast' cells in culture are derived from small lymphocytes, and assuming that the time interval $T_s - T_0$ is sufficient for all the small lymphocytes that have been stimulated to assume a 'blast' cell morphology, the index of response is given by:

$$\text{Index of response} = \frac{1{,}000\,n}{N}$$

For example, using the data in Table 2, culture *EVA/COO* has an index of response given by

$$\frac{173 \pm 5 \text{ per cent}}{2{,}000 \pm 4{\cdot}5 \text{ per cent}} \times 1{,}000 = 87 \pm 7 \text{ per cent}$$

when $T_s - T_0 = 90$ h. Similarly for *LAY/GOU* the index of response in this case is

$$\frac{297 \pm 5 \text{ per cent}}{2{,}000 \pm 4{\cdot}5 \text{ per cent}} \times 1{,}000 = 150 \pm 7 \text{ per cent.}$$

The index of response is a measure of the actual number of original small lymphocytes which undergo transformation in culture.

Allowance must be made for the lymphocytes which transform into 'blast' cells in the control cultures with no apparent stimulus. We propose that a 'corrected index of response' may be calculated by subtracting the 'blast' cell count in the control culture from the 'blast' cell count in the antigen-stimulated culture. The resulting corrected index of response indicates more clearly the responsiveness of the lymphocytes to the *in vitro* stimulus. For example, in mixed lymphocyte cultures:

If n_a is the absolute number of 'blast' cells per mm³ present at T_s in a control culture of donor a; n_b, the absolute number of 'blast' cells per mm³ present at T_s in a control culture of donor b; n_{ab}, the absolute number of 'blast' cells per mm³ present at T_s in a mixed lymphocyte culture of donors a and b; N, the original absolute number of small lymphocytes at T_0 in all three cultures, then the corrected index of response is given by:

$$\text{corrected index of response} = \frac{1{,}000\left(n_{ab} - \frac{n_a + n_b}{2}\right)}{N}$$

The number of 'blast' cells, n, is obtained by multiplying the total white cell count at time T_s by the percentage of 'blast' cells seen in the smear made from the culture. Usually the smear is made from a cell concentrate obtained by centrifuging a sample taken from the culture to increase the cellularity of the smear. It is important that centrifugation is fast enough to ensure that all cells in

the sample are spun down, otherwise there might appear to be a falsely high percentage in the smear of the denser cells from the sample. There are three possible sources of error in determining the absolute number of 'blast' cells. The first lies in the error inherent in visual cell counting technique[7]. We have also found that electronic cell counting can give false results on samples taken from cultures due to the debris present.

The second possible source of error lies in performing the differential count. Rumke[8] has shown that counts of less than 1,000 cells are only reliable to within about ±2 per cent when the minor cell population lies between 1 per cent and 10 per cent. It may be necessary to examine as many as 10,000 cells from any one sample to achieve a significant result especially as there is a tendency for blast cells to be distributed at the tail and edge of the smear.

The third and most serious problem lies in the identification of 'blast' cells in the stained smear. The fully differentiated 'blast' cell is easily recognized (Fig. 2). In wet preparations the cell has an over-all diameter of about 16μ and the nucleus is central. After spinning, smearing and staining with Romanowsky stains the 'blast' cell has basophilic cytoplasm, the nucleus may appear eccentric, and the chromatin of the nucleus in interphase appears to be a combination of a stippled and a fine reticular pattern. The nucleus may contain up to three small nucleoli or one large nucleolus. In the cytoplasm there may be azurophilic granules and small, well-defined vacuoles. 'Blast' cells in mitosis are readily recognized (Fig. 4); indeed, some workers rely on the percentage of mitotic figures in a preparation to indicate the extent of the *in vitro* response[9]. The error in determining the mitotic index is ± 30 per cent (ref. 10).

The daughter 'blast' cells shown forming in Figs. 3–7 are a source of difficulty, as with a Romanowsky stain the main detectable difference between a medium lymphocyte and a daughter 'blast' cell is the depth of cytoplasmic basophilia. With experience, however, it is possible to distinguish these forms in well-stained preparations. The use of a size threshold as a criterion for transformation can be misleading as Winter *et al.*[11] have pointed out, because it is arbitrary and may exclude transitional forms. The size of a 'blast' cell can also vary depending on its position in the smear. It has also been shown that the size of a lymphocyte smeared on a slide often bears no relation to its size in the wet state[12].

Uptake of tritiated thymidine. At present 'blast' cell production is judged visually by many workers and the index of response is an attempt to make the measurement of the 'blast' cell response meaningful, but it would undoubtedly be of value to have a parameter by which to measure 'blast' cell activity other than a purely morphological one.

Pulse labelling of lymphocyte cultures with tritiated thymidine can later be quantitated by autoradiography or liquid scintillation counting. Autoradiography is, of necessity, followed by differential counting and is thus

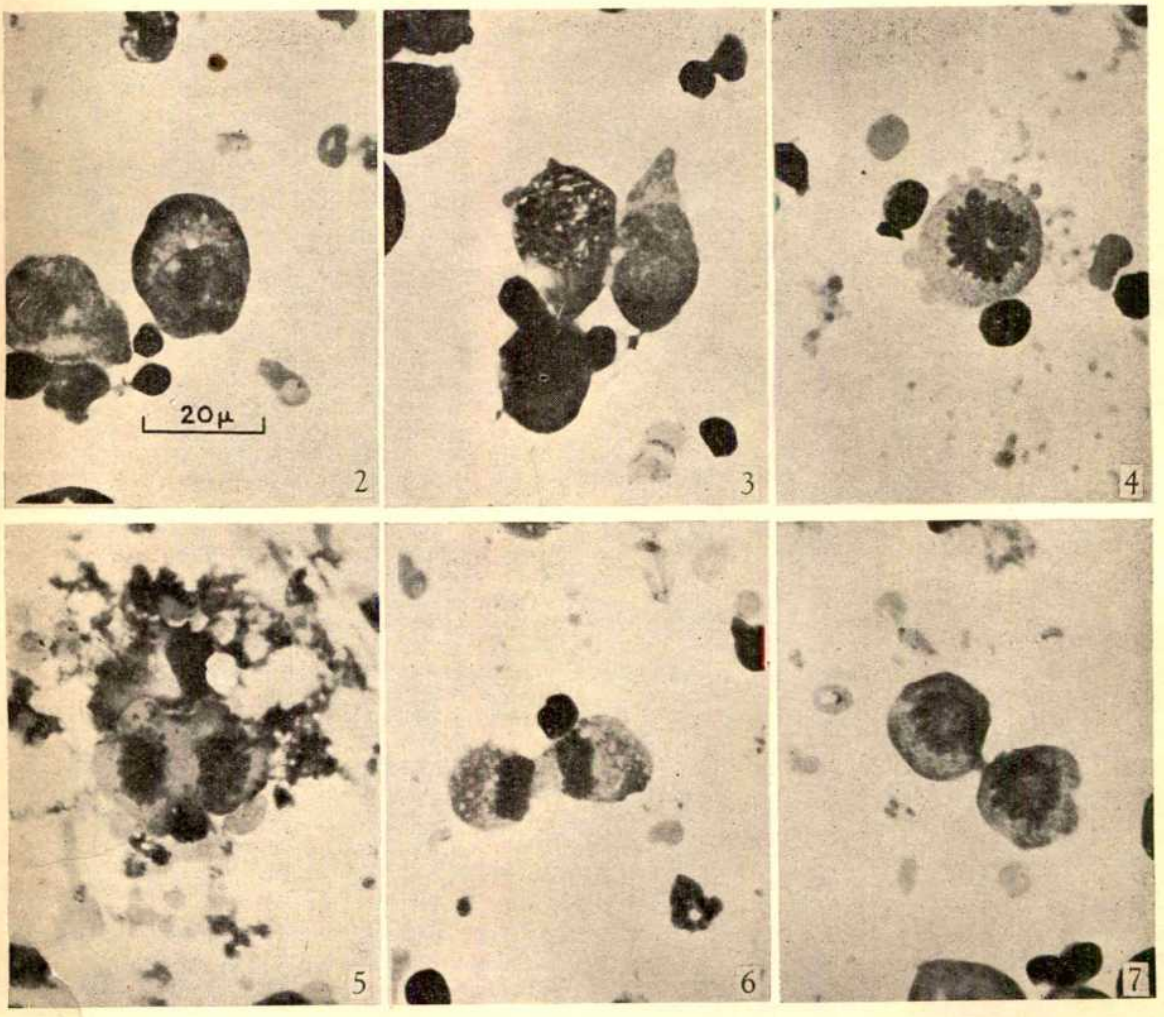

Fig. 2. 'Blast' cells. Figs. 3–7. Various stages of mitosis of 'blast' cell encountered in Romanowsky-stained smears made from lymphocyte cultures. The scale of magnification is the same for all the figures

subject to many of the errors encountered in the morphological techniques already discussed. Furthermore, autoradiography only detects those cells in the *S* compartment of the cell cycle. This information would be of greater value if it could be shown that the number of 'blast' cells in the *S* compartment bore a constant relationship to the total number of 'blast' cells present produced at the time of sampling. Our experience indicates that differential counting on Romanowsky-stained smears by eye is sensitive enough not to miss 'blast' cells that can later be identified autoradiographically.

Liquid scintillation counting detects the amount of label incorporated into the DNA of the cultured cells *en masse*. Besides the need to show a constancy of relationship between 'blast' cells in the *S* compartment and the total 'blast' cell population there is an added complication. Pelc[13] has shown that in many tissues DNA is not perfectly stable and that labelled precursors of DNA can be incorporated into non-dividing cells. It is possible that the conditions prevailing in culture may induce or exacerbate instability in the DNA of those lymphocytes which are not responding by 'blast' cell transformation. The subsequent incorporation of labelled precursors into the total DNA of the culture would thus not be correlated directly with DNA synthesis in the 'blast' cells. This would interfere with accurate quantitation.

The whole problem of quantitating a 'blast' cell response is a reflexion of the ability of the 'blast' cell to grow and divide and allowance must be made for the dynamic nature of the cell population in any attempt at quantitation. Certainly the citing of percentages of 'blast' cells at the time of sampling without simultaneous total counts is open to criticism, and in our experience may be misleading. The index of response is suggested as a method of quantitation for short-term culture and the errors in this approach have been discussed. It is to be hoped that it will prove possible to correlate the different methods used for measuring the cellular response in lymphocyte cultures, that is, labelled precursor uptake, mitotic index and the index of response.

We thank Mr. N. V. Smith, of the Cavendish Laboratory, Cambridge, for assistance with the statistics. One of us (A. S. C.) is in receipt of a grant from the Medical Research Council.

NUCLEAR STRUCTURE IN LYMPHOID PRIMORDIA

By L. T. CHEN and Prof. R. F. RUTH
Department of Zoology, University of Alberta, Edmonton

THE first lymphoid cells appear in the thymus of vertebrates and in the thymus and the bursa of Fabricius of avian vertebrates and emigrate to lymphoid tissues which differentiate later[1]. The recognition and interpretation of this phenomenon differ sharply from earlier views. Most importantly, it differs from John Beard's view that all leucocytes, including the bursa lymphocytes, are derived from the thymus[2,3]. Beard's view, brilliantly in advance of those held by haematologists, cannot account for the proliferation and differentiation of polymorphonuclear granulocytes which occur before the formation of the thymus[4]. These granulocytes cannot originate in the thymus or from emigrant thymus cells. The thymus does not exist at the time when the granulocytes appear[5]. Nor can Beard's statements be reconciled with the histological and ultrastructural evidence that the bursa lymphocytes develop from cells of the bursa epithelium[4]. These two defects in Beard's hypothesis are not generally recognized. This may be due to frequent representation of the term 'leucocyte' to mean 'lymphocyte' and fortuitous inattention to his view of the bursa of Fabricius. Beard's 'thymus' hypothesis was his final contribution to a distinguished investigation of the pharynx and its derivatives. His hypothesis was derived, in major part, from an investigation of elasmobranchii, which would seem to account for its inadequacies when applied to all vertebrates.

Beard emphasized the origin of the thymus. In *Raja batis*, and other fish[6], the thymus appears as placodes of epithelial cells at the junctions of branchial ectoderm and pharyngeal endoderm. This peculiarity would, in Beard's time, serve to distinguish the thymus from the bursa of Fabricius of birds. It was commonly believed that the bursa originates from cloacal or caudal endoderm which is relatively distant from the proctodeal ectoderm[7–9]. We now know that the bursa, like the thymus, originates at or near a point of contact between ectoderm and endoderm[10]. The present realization might well have been derived from two classical studies[11,12]. Neither study, however, attributed importance to the contact of ectoderm and endoderm. In this respect, these investigations parallel the views of most students of the mammalian thymus[13]. The principal proponent of the significance of ectodermal–endodermal contact was Edgar Norris, whose views were derived from a careful investigation of the human pharynx and its derivatives[14]. The importance of the ectoderm was confirmed experimentally in 1954 (ref. 15). If the branchial ectoderm is removed before it contacts the pharyngeal endoderm the thymus does not develop normally. The present report describes nuclear peculiarities in the region of contact between ectoderm and endoderm.

Fig. 1 represents a sagittal section through the cloaca of a 5-day-old chicken embryo. For our purpose, it is impossible to describe any one section as a true mid-sagittal section because the most important 'mid-sagittal' structure is a curved membrane which does not lie entirely within one plane. This is the urodeal membrane (*UM*) seen between the cloaca (*CL*) and the proctodeum (*PR*). The urodeal membrane is a thin, median partition which separates the right and left halves of the body. The membrane is continuous from front to rear and top to bottom except for the vesicles (Fig. 2, *BV*), which will multiply, enlarge and fuse to form the cavity of the bursa of Fabricius.

Fig. 3 is an electron micrograph of an area adjacent to a bursa vesicle (*BV*). The vesicle contains material which is precipitated by routine preparation for electron microscopy. The vesicle is bound by elongated epithelial cells linked by desmosomes and interdigitations of the

cell membranes. The nucleus (*N*) of a typical cell lies at the bottom and its nuclear membrane (*NM*) appears as a double membrane in the centre. At the arrows (→←), the outer membrane of the nuclear membrane is directly continuous with the cell membrane (*CM*). The cell membrane parallels the nuclear membrane and is closely applied to the cell membrane of an adjacent cell. Continuity between the nuclear membrane and the cell membrane has been described in the fusiform cells of Rous sarcomata[16], but we are not aware of previous reports of direct connexions in normal cells of vertebrates. We attribute the direct connexion to the elongation of the cells which surround the vesicles. This brings the nuclear and cytoplasmic membranes into proximity, which may be a necessary condition for the visualization of the connexion in one electron micrograph. The resolution obtained is at the practical limit of our equipment. Fig. 3 includes a part of a bursa vesicle (*BV*) which obviously contains precipitated materials. The formation and growth of these vesicles will be discussed elsewhere.

Fig. 4 represents a frequent feature of the nucleoli of the urodeal cells. The nucleoli contain electron-dense material which forms serpentine threads or meandering

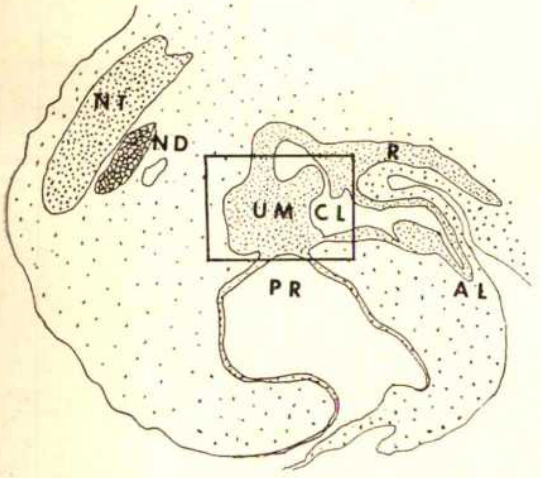

Fig. 1. A diagram of a sagittal section through a 5-day-old chicken embryo. The head lies to the right, outside the figure, and the tail curves to the left below the proctodeum (*PR*). The proctodeum is separated from the cloaca (*CL*) by the urodeal membrane (*UM*). *AL*, allantois; *R*, rectum; *NT*, neural tube; *ND*, notochord. The framed area corresponds to Fig. 2. (× *c.* 28)

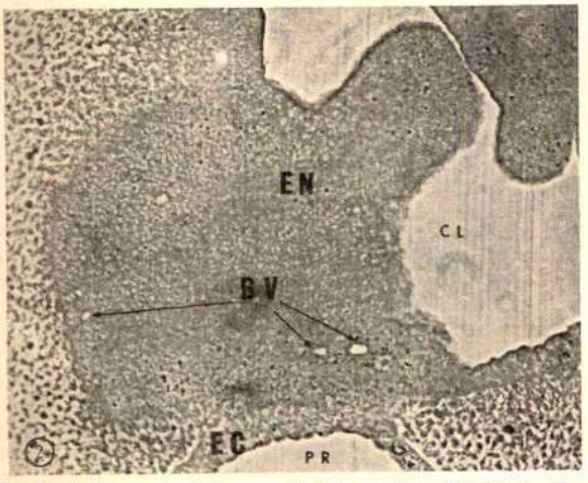

Fig. 2. A phase-contrast photograph of the area framed in Fig. 1. The vesicles (*BV*) which will fuse to form the lumen of the bursa of Fabricius are present in the urodeal membrane. The ectodermal epithelium (*EC*) of the proctodeum abuts against the endoderm (*EN*) which occupies most of the urodeal membrane. The tissue was fixed in 1 per cent osmium tetroxide, embedded in 'Araldite', and sectioned at 10μ. The photograph was taken with 'Agepe' *FF* 35-mm film, a Leitz '*n*' dark phase contrast 10× objective, and a Leitz Heine condenser. (× *c.* 120)

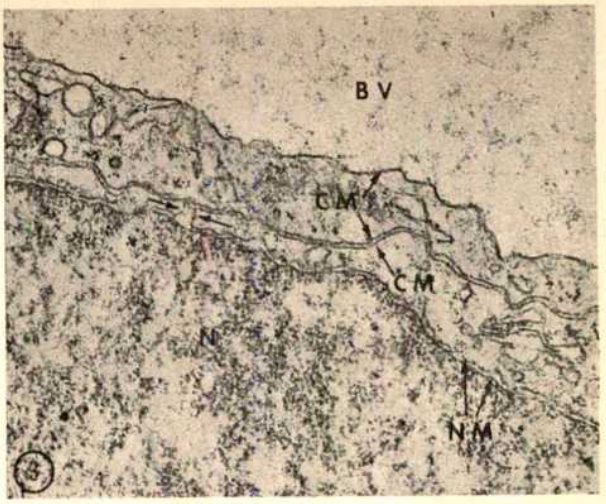

Fig. 3. An electron micrograph of part of the urodeal membrane of a 5-day-old chicken embryo. Part of a bursa vesicle (*BV*) is included. Parts of two typical, elongated cells are seen adjacent to the vesicle. Small vesicles may be seen in the cytoplasm of both cells. One of these appears as a continuation (→←) of the outer nuclear membrane (*NM*) with the cytoplasmic membrane (*CM*). *N*, Nucleus. The tissue was prepared in the same way as that represented in Fig. 2, except that the plastic sections were stained with uranyl acetate. A Phillips *EM*100*B* microscope was used with an objective aperture of 25μ. (×18,400)

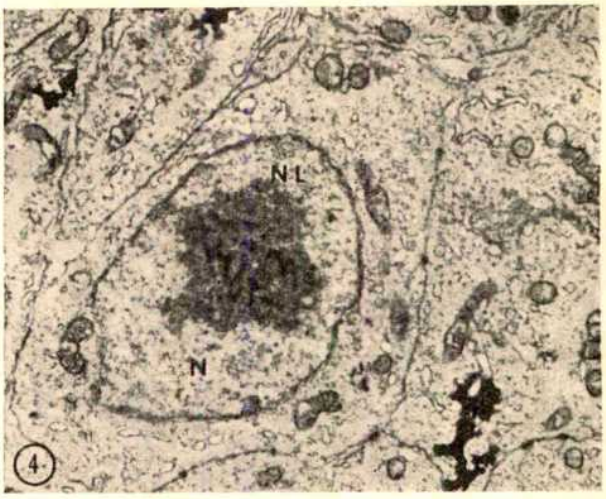

Fig. 4. An electron micrograph of the urodeal membrane of a 5-day-old chicken embryo. The dark, thread-like or membranous mass lies within the nucleolus (*NL*) of a typical nucleus (*N*). The figure was prepared to emphasize the contrast between this mass and the remainder of the nucleolus. The section was not stained with uranyl acetate. Otherwise the preparation and conditions were the same as for Fig. 3. (× *c.* 8,935)

membranes. It is difficult to imagine that these represent random aggregates of granules. The density is equivalent to that of desmosomes. The threads are found in large, dense nucleoli and do not reach the edges of the nucleoli. The only other structures in these nucleoli are the granules which are distributed uniformly. We advance no interpretation of the dense threads.

Fig. 5 represents the intimate contact (→←) of ectoderm and endoderm in the region of the thymus (←). The thymus primordium appears in the area marked by one arrow, but is in an adjacent section. Fig. 5 is selected because it shows the point of contact particularly well. Although the thymus primordium proper shows signs of active proliferation, both it and the adjacent epithelia undergo severe degenerative changes.

Fig. 6 represents a form of degeneration common in the primordium of the thymus. Normal nuclear pores (*NP*) are present in a nuclear membrane which has begun to form myelin figures. If we extend the term introduced by Hruban *et al.*[17] we might term this 'focal nuclear degradation'. This would be misleading because the

cytoplasm also forms myelin figures. Myelin figures sprout up everywhere. This is just one characteristic of a degeneration which involves the nucleus and cytoplasm of every cell in some parts of the epithelial complex. The degradation of the nucleus is a prominent feature in the formation of the thymus, but is less evident in the formation of the bursa. In the region of the bursa, the cytoplasm may undergo focal cytoplasmic degradation[17] while the nucleus remains normal. In the region of the thymus, the nucleus and the cytoplasm change and deteriorate simultaneously. The cytoplasmic changes and their relation to nuclear changes are the subject of a more detailed report.

The present report confirms the intimate contact of ectoderm and endoderm at the points of origin of the thymus and the bursa of Fabricius. This contact is associated with contrasts in cell behaviour. Many of the cells degenerate and die. Others persist to form the bursa and the thymus. The degeneration in the region of the thymus is characterized by a simultaneous degradation of the nucleus and the cytoplasm. The degeneration in the region of the bursa is characterized by degradation of the cytoplasm which precedes or is unaccompanied by degradation of the nucleus. The degeneration precedes

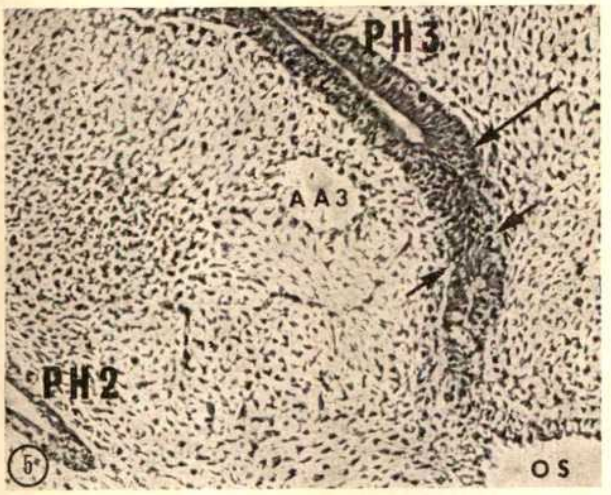

Fig. 5. A phase-contrast photograph of a frontal section through the pharynx of a 5-day-old chicken embryo. The branchial ectoderm extends inward from the outside surface (*OS*) of the body to a point (→←) adjacent to the primordium of the thymus of the third pharyngeal pouch (←). The endoderm of the third pharyngeal pouch (*PH3*) extends outward to the primordium of the thymus. The second pharyngeal pouch (*PH2*) lies to the left and the third aortic arch (*AA3*) lies between the pouches. The preparation of the tissue and photographic conditions were the same as for Fig. 2, except that the fixation with osmium tetroxide was preceded by fixation in glutaraldehyde. (× *c.* 135)

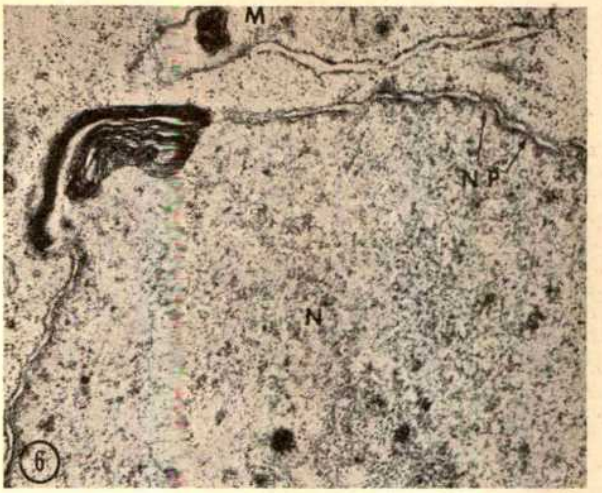

Fig. 6. An electron micrograph of the primordium of the thymus of a 5-day-old chicken embryo. Nuclear pores (*NP*) are seen in a nuclear membrane which is forming myelin figures at two widely spaced points, one of which is shown. Degradation of this type accompanies degradation of the mitochondria (*M*) in the thymus, but has not been seen in the bursa. The preparation of the tissue and the photographic conditions are the same as those for Fig. 3. (× 20,000)

the formation of the thymus and the bursa; the intimate contact between the persisting and degenerating cells suggests that the degeneration is a stimulus to the formation of the lymphoid primordia and an early step in the acquisition of specific immunological reactivity.

This work was supported by the National Research Council and the Medical Research Council of Canada. We thank Mr. G. Menges for photographic assistance, and G. R. J. Law of the Hy-Line Poultry Farms, Johnston, Iowa, for providing the embryos used.

INCREASED AORTIC BETA-GLUCURONIDASE ACTIVITY WITH PROGRESSIVELY SEVERE ARTERIOSCLEROSIS IN FEMALE BREEDER RATS

By Prof. BERNARD C. WEXLER and Dr. JOSEPH T. JUDD

May Institute for Medical Research of the Jewish Hospital and the Departments of Pathology and Biological Chemistry, University of Cincinnati College of Medicine, Cincinnati, Ohio

In previous reports we described the development of naturally occurring arteriosclerosis in both male and female rats after repeated breeding[1–4]. Microscopic arterial lesions begin to appear in male and female breeders as early as the first or second breeding. Such lesions appear first in the abdominal aorta and consist of focal sub-intimal accumulations of acid mucopolysaccharides, endothelial hyperplasia and fibrosis. With advancing arterial disease the media show pooling of acid mucopolysaccharides about individual elastic fibres, elastosis, ground substance degeneration and calcification. As the enzyme, β-glucuronidase, may be involved in mucopolysaccharide metabolism[5–7], we undertook to determine whether it might be involved in the pathogenesis of the ground substance degeneration and arteriosclerosis in breeder rats. Accordingly, this enzyme was assayed in serum, adrenal glands and aortas of virgin animals, which were free of arterial disease, and of breeder rats having

varying degrees of microscopic and grossly visible arteriosclerosis. In addition, combined histochemical and histological techniques were used in an attempt to determine whether β-glucuronidase activity could be demonstrated in areas of mucopolysaccharide accumulation in and about arterial lesions.

The animals used in this investigation were Sprague–Dawley rats obtained from the Sprague–Dawley Farms, Madison, Wisconsin. The animals were housed in air-conditioned quarters, were given tap water to drink and were allowed free access to food at all times. The diet consisted of a pelleted commercial rat diet (Texlad, Inc., Monmouth, Illinois) which has a relatively low fat content (4 per cent).

Male and female virgin rats served as controls and were comparable in age to the breeder rats. The degree of development of arteriosclerosis of the aorta was determined by gross examination at the time of autopsy. Since male breeder rats develop only microscopic lesions in the aorta, the arterial samples removed from these animals were considered as a separate class. Female breeders, however, develop varying degrees of grossly visible arteriosclerosis which are readily detected at autopsy. The arteries and tissues from these animals were separated into four classes: clear, minimal, moderate and severe, in keeping with the severity of gross arteriosclerosis found in the aorta[1]. To avoid the stress of anaesthesia at the time of autopsy, all animals were decapitated instantly by means of a guillotine. Arteriovenous blood was collected from the large severed vessels in the neck; samples of serum were prepared by prompt centrifugation. The adrenal glands were quickly removed, trimmed free of fat and extraneous tissue, homogenized in ice-cold water and filtered. The entire aorta extending from the heart down to the bifurcation into the iliac arteries was removed, weighed, stripped of extraneous tissue, cut up with fine scissors, homogenized in ice-cold water and filtered. In some investigations, specific segments of the aorta, for example, arch, thoracic and abdominal, were removed and treated in the same manner. The arch of the aorta consisted of the ascending and descending limbs of the aorta free of the innominate and carotid artery branches. The thoracic aorta consisted of that portion of the aorta between the point at which the superior vena azygos crosses the aorta down to the folia of the diaphragm. The abdominal aorta extended from the diaphragm, free of side branches, down to the bifurcation into the iliac arteries.

The method of Fishman *et al.*[8] was used with only minor modifications to determine the β-glucuronidase activity in serum or in the supernatants from homogenates of adrenal or aortic tissue. Buffered serum or an aliquot of tissue homogenate was incubated with phenolphthalein glucuronic acid as described in the original method[8] and the amount of phenolphthalein released was determined. The activity was then calculated as the amount (μg) of phenolphthalein liberated per hour—1 μg/h equalling one unit. Serum samples were incubated for 20 h, adrenal homogenates, 2·5 per cent (w/v), for 2 h, and aortic homogenates, 5–10 per cent (w/v), for 20 h.

In order to demonstrate histochemically the presence of β-glucuronidase, tissue was fixed overnight in cold chloral hydrateformalin as prescribed by Fishman and Baker[9]. Cryostat sections were cut at 8μ and stained according to the method described by Seligman *et al.*[10].

Segments of the aorta and adrenal glands were all fixed in 10 per cent buffered neutral formalin (Lillie) embedded in paraffin and sectioned at 3μ. Frozen sections were cut at 5–10μ. Haematoxylin and eosin were used for routine examination; Gomori's aldehyde fuchsin stain for elastic tissue; alcian blue and toluidine blue for demonstration of metachromasia and acid mucopolysaccharides as well as the Hale stain; the von Kossa method for calcium; and Sudans II and III, oil red O and Sudan black *B* for the demonstration of lipids in the frozen sections.

No significant differences were found in the serum levels of β-glucuronidase between virgin rats without arterial disease and breeder rats with either microscopic or gross arteriosclerosis (Table 1). Although the adrenal glands contained a considerable amount of β-glucuronidase activity, no significant differences could be found between animals with and without arterial disease (Table 1). Furthermore, no difference could be demonstrated between the β-glucuronidase activity of adrenal glands from male or female rats (Table 1).

Table 1. β-Glucuronidase Activity in the Serum and Adrenal Glands of Virgin and Breeder Rats

Sample	Virgins, No arterial disease, Males*	Virgins, No arterial disease, Females*	Breeders, Microscopic arteriosclerosis, Males*	Breeders, No grossly visible arteriosclerosis, Females*	Breeders, Gross arteriosclerosis, Females*
Serum† (units/0·1 ml. ± *S.D.*)	1·13 ± 0·17	1·35 ± 0·26	1·12 ± 0·14	1·21 ± 0·16	1·26 ± 0·23
Adrenals† (units/mg ± *S.D.*)	3·05 ± 0·46	3·23 ± 0·84	2·33 ± 0·78	3·54 ± 0·50	3·42 ± 0·72

* Number of samples for each determination was 5.
† One unit of activity equals 1 μg of phenolphthalein released per h.

Significant increases, however, were found in the β-glucuronidase activity of aortas taken from female breeders with advanced gross arteriosclerosis (Fig. 1). These increases paralleled the severity of arteriosclerosis; that is, aortas from female breeders with moderate or severe gross arteriosclerosis had the greatest enzyme activity (Fig. 1). There was no significant difference in enzyme activity of the aorta between male virgin controls with no arterial disease and the male breeders with microscopic arterial lesions (Fig. 1).

Separation of the aorta of female breeder rats with varying degrees of gross arteriosclerosis into three anatomical segments, that is, arch, thoracic and abdominal, revealed striking differences in enzyme activity in these segments (Fig. 2), which coincided with: (*a*) the anatomical progression of arteriosclerosis as it develops and spreads in these animals; (*b*) the increasing severity of the disease.

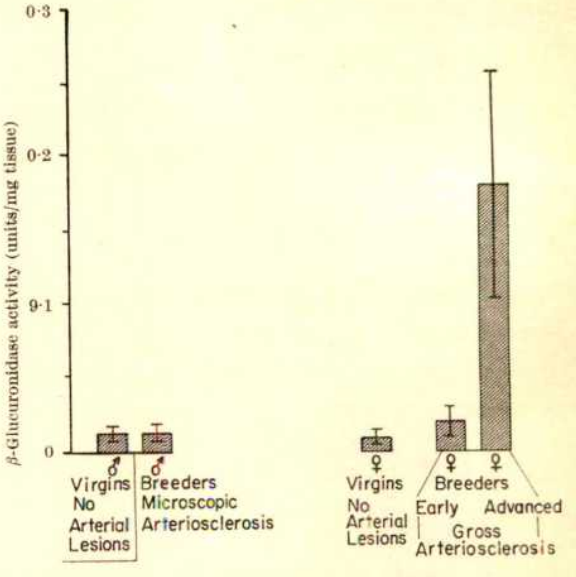

Fig. 1. Average β-glucuronidase activity of whole aortas (± *S.D.*) removed from male and female virgin rats having no arteriosclerosis (controls) compared with aortas removed from male breeders having microscopic arterial lesions only and with female breeders having either early or advanced gross arteriosclerosis. One unit of β-glucuronidase activity equals 1 μg of phenolphthalein released per h. Statistical comparison (using the '*t*-test') shows that there is no significant difference ($P > 0.05$) between the aortas of virgin rats and aortas of breeder rats having only early gross arteriosclerosis. However, highly significant differences were found among the aortas of virgin females with no arteriosclerosis and female breeders with advanced gross arteriosclerosis, $P = \ll 0.005$. (Five samples of aorta were used in each of the classes depicted)

In the female breeder rats the aortas of which showed no grossly visible lesions, that is, 'clear' (these grossly clear aortas, however, contain microscopic arterial lesions), no real differences could be determined between the three aortic segments. However, in female breeders with minimal gross arteriosclerosis, where the gross arterial plaques can be seen in the abdominal aorta only, β-glucuronidase activity was significantly elevated in only the abdominal aorta (Fig. 2).

In female breeders with moderate arteriosclerosis, where grossly visible plaques could be detected first in the abdominal and secondly in the arch segments of the aorta, the β-glucuronidase activity was significantly elevated in these two segments, specifically (Fig. 2). The thoracic aorta, which displays no grossly visible plaques in female breeders with moderate arteriosclerosis, showed no significant increase in β-glucuronidase activity (Fig. 2).

Female breeders with severe gross arteriosclerosis showed a significant increase in β-glucuronidase activity in all segments of the aorta (Fig. 2) in keeping with the presence of advanced arteriosclerosis throughout the aorta of such animals.

In general, a clear, step-wise trend toward increased aortic β-glucuronidase activity was noted within each of the aortic segments concomitant with increasing severity of arterial disease, that is, clear, minimal, moderate and severe.

Chemical analyses of aortic β-glucuronidase activity agreed well with the histochemical demonstrations of the enzyme. The enzyme was demonstrable histochemically

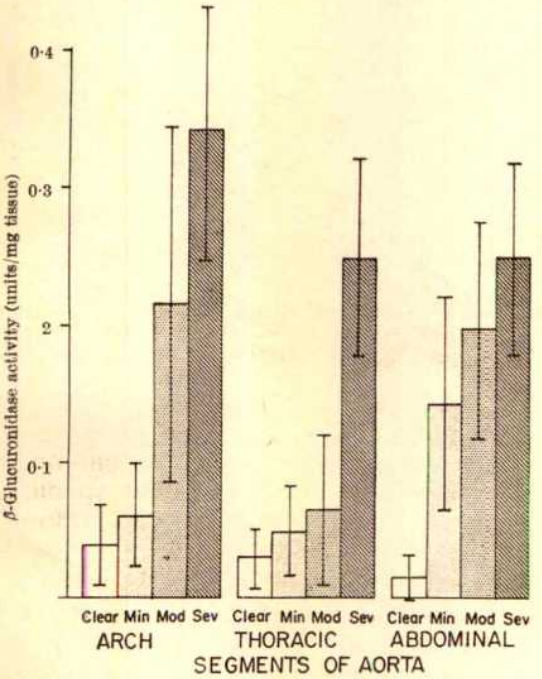

Fig. 2. Average β-glucuronidase activity of the arch, thoracic, and abdominal aortic segments (± *S.D.*) of aortas removed from female breeder rats having varying degrees of gross arteriosclerosis ranging from clear to minimal to moderate to severe. One unit of β-glucuronidase activity equals 1 μg of phenolphthalein released per h. Statistical treatment of the data by the method of analysis of variance showed that there was a highly significant difference in aortic β-glucuronidase activity ($P = < 0{\cdot}01$) among the various classes of arterial pathology in all aortic segments. Grouping of the arterial pathology classes within each aortic segment into those manifesting early versus advanced arteriosclerosis, for example, within the abdominal aorta, clear versus minimal + moderate + severe; within the aortic arch, clear + minimal versus moderate + severe; within the thoracic aorta, clear versus minimal + moderate + severe, statistical application of the '*t*-test' showed that, in all cases, there was a highly significant increase in aortic β-glucuronidase activity in the arteriosclerotic aortas commensurate with advancing severity of the arteriosclerosis ($P = < 0{\cdot}001$). (Seven separate samples were used throughout for each of the varieties of aortic samples depicted, except in the case of those with 'severe' arteriosclerosis where nine samples were used for each case, that is, a total of ninety individual aortic samples were investigated)

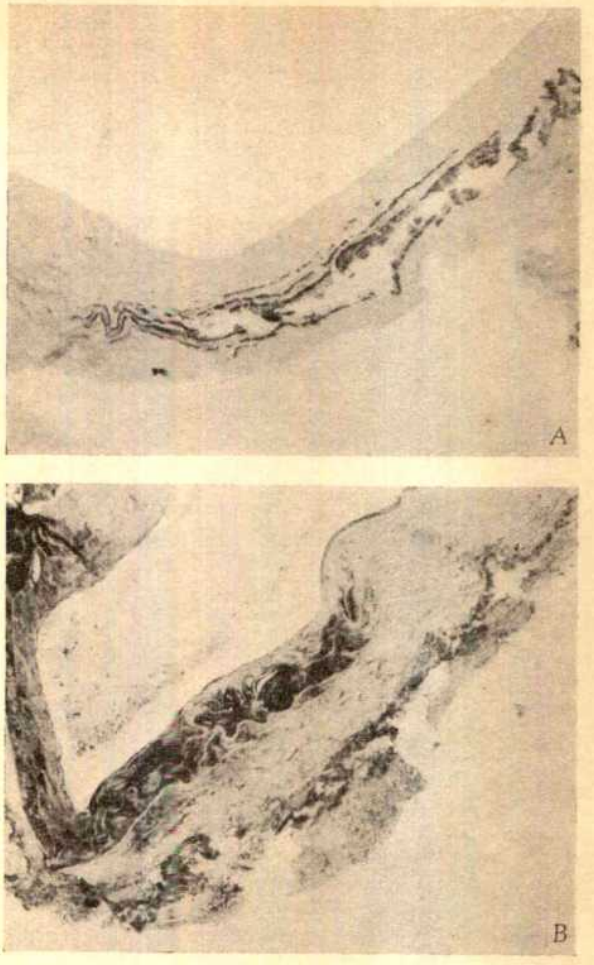

Fig. 3. *A*, Cryostat section of an aorta taken from a female breeder rat which had moderate gross arteriosclerosis. Positive β-glucuronidase activity (deep black material in figure) is found concentrated about individual elastic fibres. These same sites also contain much acid mucopolysaccharide (compare 3*B*) and calcium (× 37·5). *B*, Paraffin section stained for acid mucopolysaccharides (Hale stain), pooling of mucopolysaccharide (deep black material in figure) about degenerating elastic fibres which appear as white wavy lines (× 75)

in those arterial segments with the more advanced and complicated arteriosclerotic lesions. The aortas of virgin rats free of arteriosclerosis, and of breeder rats with microscopic arterial lesions only, showed no trace of β-glucuronidase activity.

The most intense positive reaction for β-glucuronidase was concentrated in the media, particularly in areas of degenerating ground substance and around elastic fibres which were undergoing dissolution (Fig. 3). Medial sites of dystrophic calcification also showed substantial enzymatic activity. In foci of cartilaginous metaplasia, the individual cartilaginous cells displayed a halo which reacted positively for β-glucuronidase.

In some aortas, particularly those with advanced arteriosclerosis, a diffuse positive reaction for the enzyme was observed in the media often accompanied by a very strong positive reaction in the adventitia. Those medial foci which were intensely basophilic (with haematoxylin), strongly metachromatic, and which reacted positively with alcian blue and to the Hale stain showed the greatest enzyme activity. Since the spleen has a very high level of β-glucuronidase activity, sections of spleen were tested simultaneously as control tissues together with the aortic tissue. The sections of spleen were intensely positive for the enzyme.

Unlike aortic tissue, the adrenal glands showed a much more positive reaction for β-glucuronidase. The zona (z.) glomerulosa showed only slight positive enzyme activity

in virgin rats and no activity in breeder rats. In the virgin rats, male and female, the outer portion of the z. fasciculata was intensely positive for the enzyme, but the z. reticularis and inner portions of the z. fasciculata were completely free of enzyme activity.

In breeder rats, both the z. fasciculata and the z. reticularis displayed enzyme activity but much less intense than that observed in the outer z. fasciculata of virgin rats.

The details of the histological changes involved in the pathogenesis of arteriosclerosis in breeder rats have been reported[1-4]. The earliest changes seen in the aortas of breeder rats consisted of a focal aggregation of basophilic cell elements both in the intima and media. These cells are surrounded by a metachromatic substance, probably acid mucopolysaccharide, and are either mesenchymal cells or smooth muscle cells. Large quantities of acid mucopolysaccharides appear in the intimal space and become transformed into fibrotic plaques.

With advancing arteriosclerosis the media show generalized accumulation of acid mucopolysaccharides between medial muscle cells and concentrated pooling about individual elastic fibres. In scattered foci the elastic fibres and ground substance undergo degeneration followed by haemorrhage and necrosis. The accumulation of acid mucopolysaccharide is intense in those loci which become filled-in or repaired either by cartilaginous metaplasia or dystrophic calcification.

The finding of significant increases in aortic β-glucuronidase activity with increasing severity of arteriosclerosis in breeder rats is interesting because changes in β-glucuronidase activity may be associated with: (*a*) mucopolysaccharide metabolism[6,7]; (*b*) active cell proliferation, for example, arteriosclerosis[6,7] or cancer[5,11,12]; (*c*) cyclic changes within the female sex organs accompanied by a rise and fall in enzyme activity during menstruation and pregnancy[5,9,13]; (*d*) increased enzyme activity in various endocrine glands and in serum in response to adrenal steroids[14-16], stress and Cushing's disease[17]. The arteriosclerosis which develops in breeder rats is similarly also associated with: (*a*) marked alterations in the mucopolysaccharides of aortic ground substance; (*b*) a remarkable sex difference in the nature of the development of the arteriosclerosis and the mucopolysaccharide changes; (*c*) marked activity of the reproductive system, particularly apparent in the female; (*d*) equally marked changes in adrenal steroid function[18] and histology[19], accompanied by degenerative changes associated with hyperadrenocorticism.

The increase in arterial enzyme activity was not reflected through any apparent change in serum levels. However, these breeder rats were examined several weeks *post partum* when serum enzyme activity would be at its lowest level[11,13,20-22].

The results of the chemical analyses of adrenal β-glucuronidase activity provided no clue as to how this enzyme in the adrenal cortex might participate either in changes in cortical function *per se* or in the enzyme changes observed within the arterial wall.

However, the histochemical testing of adrenal gland slices revealed specific zonal differences in the concentration and distribution of β-glucuronidase, that is, absence of β-glucuronidase in the z. reticularis of adrenals of virgin rats which have no arterial lesions compared with its presence in this zone in arteriosclerotic breeder rats. This condition could be a reflexion of altered 17-ketosteroid production in breeders.

The significant increase in aortic content of β-glucuronidase in female breeders with increasing severity of gross arteriosclerosis is particularly meaningful and provocative. Kirk[6] reported that although the activity of this enzyme was relatively low in normal human aortas, it did become elevated in arteriosclerotic aortas. Kayahan[23] claims that β-glucuronidase activity is low in the serum of animals prone to develop atherosclerosis and high in those resistant to atherosclerosis. In our work the enzyme activity consistently coincided with the anatomical progression of the disease in breeder rats. This is especially well illustrated in the case of female breeders with moderate arteriosclerosis (see Fig. 2). Although high enzyme activity was demonstrated in both the plaque-ridden arch and abdominal aortic segments, the thoracic segment, free of any gross plaques and serving as an internal control, was devoid of any significant enzyme activity.

The close association of enzyme activity with ground substance degeneration and acid mucopolysaccharide accumulation is in accord with the findings of Zemplényi *et al.*[7]. These investigators also found, just as we did, increased enzyme activity in medial smooth muscle cells and endothelium. Furthermore, they found increased β-glucuronidase activity in cholesterol-fed rabbits preceding the development of any recognizable arterial lesions[7].

The appearance of arterial lesions in first the abdominal and later the arch and thoracic segments of the aorta of female breeders may be due to physico-chemical differences between the arterial segments conditioned by female sex hormones. In this connexion, Malinow *et al.*[24] and Christie and Dahl[25] have shown that there are cyclic changes in aortic oxygen consumption associated with sexual activity in female rats and that the aerobic and anaerobic metabolism of the rat aorta is under the influence of gonadal hormones. Similarly, Bertelsen[26] has shown that mucopolysaccharides, the sulphated mucopolysaccharides in particular, tend to accumulate in tissues having a low oxygen tension. We have also observed considerable differences in calcium, hydroxyproline (as an index of collagen content) and mucopolysaccharide between aortas of male and female breeder rats, between aortas with early and advanced arteriosclerosis and between the various segments of the aorta[27].

RADIO ASTRONOMY

High-resolution Spectra of Decametric Radio Bursts from Jupiter

A PREVIOUS experiment relating to the fine structure in the dynamic spectra of decametric radiation from Jupiter[1,2] was repeated during the 1964 apparition of the planet, but using different techniques of observation.

The main instrument was a high-resolution multi-channel spectrograph. The centre channel was tuned to 19·0 Mc/s and the others at 50-kc/s intervals on both sides of it—their 3 and 40 dB band-widths being 5 and 50 kc/s, respectively. The number of channels varied from 10 to 14. The dynamic spectra were recorded photographically from intensity-modulated indicators, the time constant of integration being 30 msec. The aerial was a two-element collinear array with driven reflectors.

Two phase-switching interferometers were used to identify the Jovian radio bursts. One was of a panoramic type sweeping, repeatedly every 6 sec, the range 20–15 Mc/s. The dynamic spectra with phase were recorded on colour film from an intensity-modulated white-phosphor cathode-ray tube display, in front of which a colour disk with red and green segments was synchronized to rotate with the broad-band phase-switch. The other interferometer was of a single-frequency type (working at 19·3 Mc/s) driving a pen recorder. The aerials consisted respectively of two horizontal biconical dipoles with reflecting screens, and two three-element Yagi aerials, the baselines extending a few wave-lengths in the east–west direction.

The multi-channel spectrograph was operated for 4–5 h each night from September 1 to December 15, 1964, and the other receivers continuously over the same period. Almost no local interference was experienced at either of the two isolated sites of observation and the low night-time values of the ionospheric critical penetration frequency resulted in the absence of long-range interference during the Jovian transits.

Only the strongest bursts were recorded with the high-resolution equipment, the total number of nights with activity being 33. Most of the recordings showed roughly similar variations of intensity with time from channel to channel, indicating radiation band-widths of the order of 500 kc/s or more, the durations ranging from a few seconds to a few tens of seconds. On 14 nights recordings were obtained in which the variations were not similar at all, indicating fine structure composed of pulses with band-widths of the order of 50 kc/s or less. The duration of pulses varied from the time resolution of the instrument to a few seconds. A typical spectrum is reproduced in Fig. 1.

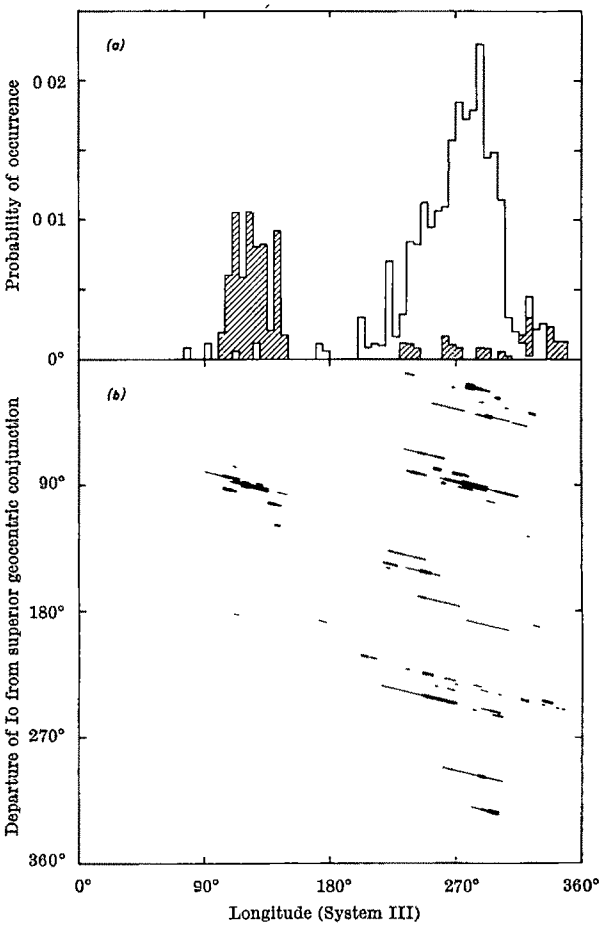

Fig. 2. (*a*) Probability of occurrence plotted against System III longitude. Recordings that are dissimilar from channel to channel are denoted by shaded areas and those that are on average similar by unshaded areas. (*b*) The radio storms observed in high resolution plotted on System III longitude and the position of the satellite Io

The probability of occurrence as a function of System III central meridian longitude[3] is shown in Fig. 2*a*, the shaded profile denoting narrow-band structure. The relatively low over-all gain of the multi-channel installation results in low values of probabilities. Following the precedence of Bigg[4] the storms are plotted in Fig. 2*b* on the co-ordinate system of the longitude of the Jovian satellite Io in its orbit, measured from superior geocentric conjunction[5], and the radio longitude. Here the width of the lines is closely related to the total duration of the bursts in equal intervals of observing time.

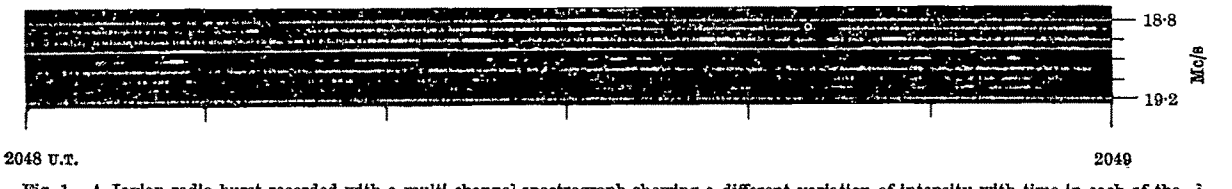

Fig. 1. A Jovian radio burst recorded with a multi-channel spectrograph showing a different variation of intensity with time in each of the channels, tuned at 50-kc/s intervals. System III longitude is 122°

It is worth noting that the trains of short-duration pulses observed in 1963 (refs. 1 and 2), which occurred at radio longitudes of the central meridian of 140°–190° and Io's position of 55°–75°, seem to be a different spectral phenomenon, although they were not recorded with certainty in 1964.

It is possible that these observations indicate some variations in the spectral fine structure depending on the positions of the radio system and the satellite Io. Various authors[6,7] have discussed the Jovian decametric emissions presuming some kind of exospheric disturbances; the extension of the present experiment to weaker radio storms would probably have some interest in studying the nature of the disturbances produced by the satellite.

ASTROPHYSICS

Interstellar Grains and the Diffuse Galactic Light

Present knowledge of the physical nature of the interstellar grains is based principally on interpretations of the observed extinction and polarization of starlight. Some scattering of the galactic radiation field by the interstellar grains must occur and it is recognized that a precise determination of the brightness of such a diffuse galactic light can also contribute to our knowledge of the grains. Since the first investigations of the diffuse light by Elvey and Roach[1] in 1937 there have been further studies by Henyey and Greenstein[2], van Houten[3] (using the measurements of the brightness distribution in the Milky Way by Elsässer and Haug[4]) and Roach and Smith[5]. Unfortunately the results of these four investigations are in considerable disagreement. Two important sources of this disagreement arise from uncertainties in assessing (1) the contributions to the observed brightness of the airglow, zodiacal light and light scattered by the Earth's atmosphere; (2) the contributions from faint stars, the integrated starlight.

This communication reports a new determination of the brightness, D, of the diffuse galactic light based on measurements secured from a sounding rocket. These measurements were obtained from altitudes above 180 km and consequently corrections for scattering and extinction in the atmosphere and for contamination by airglow (see Packer[6]) are not required. The night-sky photometer, containing a standard B filter and with a field of view of 2·7 square degrees, was flown aboard an *Aerobee* 150*A* rocket launched from the White Sands Missile Range on September 15, 1964, at 0235 h M.S.T. Observations were made along three great circle scans crossing the galactic plane at longitudes l^{II} = 53°, 66° and 164°. To derive D, it was necessary to subtract the zodiacal light and integrated starlight contributions from the measured brightness. The zodiacal light at low galactic latitudes was derived as follows: the zodiacal light away from the galactic plane was determined before and after the galactic crossing by subtracting the integrated starlight (well determined for $b^{II} > 20°$) from the total brightness; the zodiacal light at low galactic latitudes was then obtained from the foregoing by interpolation. The zodiacal light changed only slowly along the three scans so that this procedure introduced a small error in D of less than 10 (expressed in units of $n(B)$ = the equivalent number of stars of magnitude B = 10·0 per square degree).

It has already been noted that there is an uncertainty in the integrated starlight contribution. Two independent determinations by Bottlinger[7] and by Roach and Megill[8], based on different star counts, show good agreement only at latitudes $b^{II} > 20°$. The sources of this disagreement have been discussed by Henyey and Greenstein[2], van Houten[3] and Roach and Smith[5], but no definite conclusions have been drawn. In interpreting the present measures we shall assume that the integrated starlight contribution lies in the range of values derived by Bottlinger[7] and Roach and Megill[8]. The resulting values of D are given in Table 1. The numbers in columns 4 and 5 with and without parentheses correspond to values based on the starlight correction from Bottlinger[7] and Roach and Megill[8] respectively. The maximum values of D for the three galactic crossings are:

l^{II}	b^{II}	D (units of $n(B)$)
53°	−8°	76 ± 20
66°	−4°	159 ± 29
164°	−6°	61 ± 14

We remark that the diffuse light is centred several degrees south of the galactic plane, as found earlier by Henyey and Greenstein[2].

Before comparing these values with the results of earlier studies we draw attention to the conclusion of Roach and Smith[5] that the calibrations used by Elvey and Roach[1] and by Elsässer and Haug[4] most probably give brightnesses too high and too low respectively (for both the zodiacal light and the integrated galactic light). The present investigation supports this conclusion. In Table 2 we have listed the results of three determinations of the diffuse light, D, omitting the results of Elvey and Roach[1] and Elsässer and Haug[4] because of the uncertainty in calibration. The mean value of all determinations in Table 2 is $\bar{D} = 81 \pm 11$.

In concluding this communication we use the values of D in Table 2 to place a lower limit on the mean albedo

Table 1. Surface Brightness of the Diffuse Galactic Light at Three Galactic Longitudes

l^{II}°	b^{II}°	Observed integrated galactic light	Integrated starlight		Diffuse galactic light, D	
46	−12·3	118	80	(73)	38	(45)
50	−9·9	160	92	(83)	68	(77)
53	−7·7	175	106	(91)	69	(84)
57	−5·5	177	120	(98)	57	(79)
61	−2·8	164	147	(107)	17	(57)
65	−12·3	111	82	(75)	29	(36)
66	−7·0	192	99	(84)	93	(108)
66	−3·6	269	125	(95)	144	(174)
67	−1·7	230	141	(97)	89	(133)
67	4·0	134	95	(74)	39	(60)
67	9·3	83	60	(53)	23	(30)
165	−1·2	138	120	(80)	18	(58)
164	−5·9	119	63	(52)	56	(67)
163	−10 4	91	44	(40)	47	(51)
163	−15·0	59	39	(36)	20	(23)

The brightness unit is the equivalent number of stars of magnitude B = 10·0 per square degree = $n(B)$.

Table 2. Brightness of the Diffuse Galactic Light found by Different Authors (in Units of $n(B)$) and the Corresponding Minimum Albedo γ_{min} at $\lambda \simeq 0{\cdot}45\mu$

Authority	l^{II}° →	40	53	66	140	164	Average
Henyey and Greenstein[2]		106 ± 34			52 ± 20		
Roach and Smith[5]							32 ± 10
Wolstencroft and Rose			76 ± 20	159 ± 29		61 ± 14	
	γ_{min} →	0 55 ± 0·30	0·45 ± 0 16	0 65 ± 0·18	0 51 ± 0 32	0·53 ± 0·17	0·24 ± 0 13

of the interstellar grains. If the grains are perfect forward scatterers they will produce the maximum diffuse light for a given albedo γ. This fact can be used to place a lower limit on γ. In this case the relation between γ and the brightness of the diffuse light D and integrated starlight I is:

$$\gamma = \frac{D}{D+I} \cdot \frac{1}{1-e^{-\tau_0}} = \gamma_{min}$$

(see Henyey and Greenstein[2]), where τ_0 is the optical depth in the direction of observation. We do not attempt to place an upper limit on γ since its value is critically dependent on two unknowns—the asymmetry of the phase function and the value of τ_0. The values of γ_{min} (at $\lambda \simeq 0{\cdot}45\mu$) corresponding to $\tau_0 = \infty$ are given in Table 2. The mean value of these determinations is $\bar{\gamma}_{min} = 0{\cdot}49 \pm 0{\cdot}11$, which is close to the value of $\bar{\gamma}_{min}$ based on the present measurements alone. We conclude that there is an even chance that $\gamma > 0{\cdot}49$; it is practically certain that $\gamma > 0{\cdot}38$. A more detailed description and discussion of this work will be given in a forthcoming publication.

High-energy Astrophysics and a Possible Sub-nuclear Energy Source

Energy is always released when, due to the natural interactions, more bound states are formed from less bound states. This happens, for example, during the gravitational contraction of a given mass, the energy release being related to the long-range gravitational attraction and to the macroscopic properties of the matter. This is also true of nuclear reactions, when the process is connected with the nuclear structure of the matter and the short-range nuclear interactions.

As is well known, these two processes seem to be sufficient to explain the stellar energy sources. However, the enormous energy release in some extragalactic (and probably cosmological) phenomena, such as the radiogalaxies and the quasi-stellar sources, poses once again the problem of energy sources in astrophysics.

The energy required in these violent events can reach about 10^{60}–10^{62} ergs and perhaps even more, corresponding to about 10^6–10^8 $M_\odot c^2$. The associated time-scale is probably not larger than 10^5–10^6 years. Since the efficiency of the nuclear reactions is rather low (less than about 1 per cent of the mass can be converted to energy), the release of 10^{60}–10^{62} ergs would require the nuclear transformation of more than 10^8–10^{10} $M_\odot$. This seems rather unlikely on such a short time-scale.

The other possibility, that is, the release of gravitational energy in the contraction of large masses, has been investigated by many research workers (see, for example, refs. 1–3). The problem is of interest *per se* and poses some fundamental questions in physics[4]. However, the binding energy of a configuration in general relativity is different from that derived by the use of Newtonian theory, and the maximum amount of energy available from a contracting mass M is not given by $G\frac{M^2}{R_s} = \frac{1}{2}Mc^2$ (R_s is the Schwarzschild radius $\frac{2GM}{c^2}$). The energy released due to the contraction from infinity to the radius, R, is given by the binding energy: $B.E. = (M_0 - M)c^2$, where M is the observable mass of the configuration with radius R, and M_0 is the original mass when the particles are dispersed to infinity. Many authors have shown that for some configurations we have $M > M_0$ (refs. 5–7 *et al.*). It is clear that these configurations cannot be obtained by spontaneous contraction.

More clearly, Fowler[5] showed that the binding energy of a contracting sphere in a post-Newtonian approximation contains a negative term and that, because of the presence of this term, the binding energy does not monotonously increase when the radius of the configuration decreases. The binding energy increases up to a certain radius, but further contraction gives rise to less bound states. Thus the energy available through the collapse is much less than $\frac{1}{2}Mc^2$ and its exact value depends on a detailed investigation of the properties of contracting relativistic configurations.

From another point of view, no direct evidence exists for the occurrence of the gravitational collapse, since the evidence is only for explosive phenomena.

It is difficult to understand why the contraction of a given system with a total mechanical negative energy would give rise to a subsequent expansion of the same system, since the expansion demands that the energy be positive. It is necessary to assume that during the collapse of a central unobserved configuration the energy is transferred to the outer region. The sum of the energies in the internal and external regions is always negative if no other energy source is available. For these reasons, it is interesting to consider other possible energy sources.

A first proposal, initially suggested by Burbidge and Hoyle[8] and extensively investigated by Alfvén in a recent paper[9] concerns the possibility of matter–antimatter annihilation. There is another possibility for energy release in a sub-nuclear process which is based on the idea of a compound structure of the elementary particles.

We shall assume the quark's model of hadrons in the $SU(3)$ and $SU(6)$ theory of strong interactions. However, these considerations could be made in the framework of any theory based on the idea that the elementary particles are bound states of more fundamental unities.

In the quark's model the mesons are composed of a quark and an anti-quark and the baryons are the bound state of three quarks (for further details see, for example, ref. 10).

Since the experimental search for quarks gives a lower limit for their mass of about 5 GeV, the formation of the normal matter starting from the quarks would be extremely exoenergetic. However, this process is possible only in a situation of very high density, during which the distance between the quarks is of the order of, or less than, the range of the forces which cause the superbinding.

The order of magnitude of this distance is given by the Compton wave-length of the bound state. For the proton the Compton wave-length is:

$$\lambda_c = \frac{\hbar}{pc} \sim 1{\cdot}3 \times 10^{-13} \text{ cm}$$

which corresponds to a minimum density for the quark's matter of about 2×10^{14} g cm^{-3}.

A knowledge of the statistical properties of the quarks would make it possible to compute the relative concentration of quarks and hadrons under given physical conditions. This can be done in a way similar to that used by Ambartsumian and Saakian[11] to analyse the composition of a superdense gas of elementary particles.

Since this primordial matter would have a density much greater than that corresponding to the gravitational radius of large masses, the cosmic explosions could represent the delayed Friedman expansion of some regions in the primeval universe as suggested by Novikov[12].

It is, however, difficult to suppose that this process is the general cosmogonical process. If all matter were created in this way, the universe would be extremely hot and there would be a large diffuse flux of X-rays. I hope to be able to give more details on this point in the near future.

Finally, I would like to point out that if the quarks exist at low concentration in the stars, their mutual binding is rather unlikely under normal stellar conditions. However, at the end of stellar evolution very high densities and temperatures can probably be reached and the quarks can 'burn'. The related emission of high-energy particles from the super-dense star could produce phenomena similar to those observed in cosmic ray physics and in some celestial regions (X-rays, optical- and radio-emission).

I was the recipient of a European Space Research Organization fellowship during the course of this work. I thank Prof. E. Schatzman for stimulating discussions and hospitality at the Institut d'Astrophysique, Paris. I also thank Prof. L. Gratton and the members of the Astrophysical Laboratory, Frascati, for discussions on high-energy astrophysics, and Dr. F. Strocchi for advice.

PHYSICS

Auroral Effects and Excess Energy Electrons

Auroral displays are usually attributed to increased leakage of electrons from the outer radiation belt. The mechanism responsible for this increased leakage is not yet understood, but the leakage is known to occur following the arrival of corpuscular radiation from the Sun. The time delay between solar eruptions and the onset of auroral phenomena shows that any solar electrons involved must have energies below 100 eV. Because, on the other hand, auroral electrons typically have energies in the range of several tens of keV, an electron acceleration mechanism must exist, presumably within the radiation belt. The purpose of this communication is to point out similarities between auroral effects and laboratory observations of electron leakage from a magnetic mirror, accompanied by electron acceleration, and to suggest that the same basic mechanism may play a part in both cases.

Previously it was shown[1] that through space-charge oscillations electrons confined in a Penning type structure can acquire abnormally high energy, and that such excess-energy electrons readily diffuse across magnetic lines of force[2]. These effects appear if the electron current injected into the system exceeds a critical value. The present experiments extend these observations to electron confinement in a magnetic mirror.

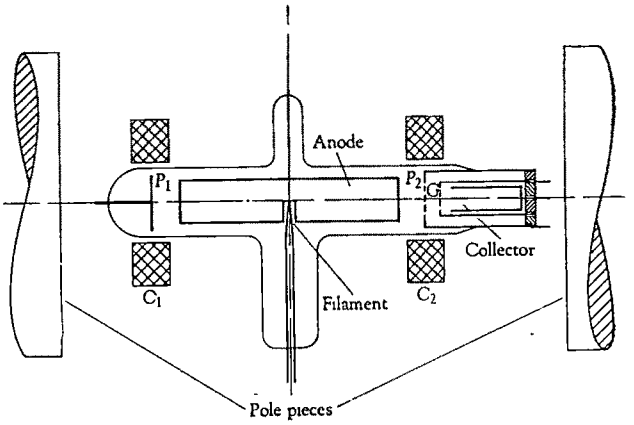

Fig. 1. Experimenta larrangement

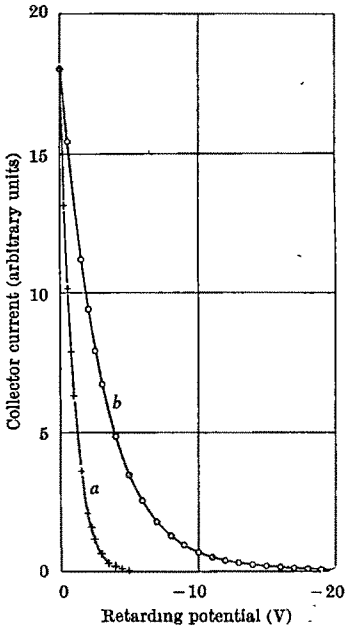

Fig. 2. Retarding potential curves. *a*, Without mirror field; *b*, mirror coils energized

The experimental arrangement is shown in Fig. 1. Thermionic electrons from a filament are injected into an open anode cylinder, which they are prevented from reaching by applying a sufficiently strong uniform axial magnetic field. The electrons therefore move along the field lines to the end plates P_1 and P_2, which are positive with respect to the filament. A sample of these electrons passes through small holes in P_2 and is subjected to a retarding potential analysis by means of the grid G, which is placed at a variable potential V_r, negative with respect to the filament. Fig. 2*a* shows a typical retarding potential curve obtained in this way. The collector current becomes zero at $V_r \simeq -5$ V, a value which can be accounted for by the heater voltage (about 4 V) and the initial velocities of thermionic emission. By energizing the two coils C_1 and C_2 the magnetic field can be made to assume mirror geometry, and the electrons then tend to be confined within the anode cylinder. When a certain degree of confinement has been achieved, space-charge oscillations suddenly set in and impart excess energy to the electrons. A typical retarding potential curve under these conditions is shown as Fig. 2*b*, where it is seen that the average energy of the electrons passing through the mirror field has been considerably increased, and that excess energies up to at least 20 eV are measurable. The magnitude of the excess energy depends on the injected electron current, the

magnetic field configuration and presumably also the geometry of the system.

The effects described resemble those encountered in auroral phenomena. It seems likely that the arrival of comparatively slow electrons from a solar flare in the radiation belt raises the charge density within the belt beyond the threshold-level required for the appearance of excess-energy electrons, and these high-energy electrons leak out into the auroral zone.

I thank Dr. W. Schwietzke for his interest in the work, and Messrs. L. Bessant and I. Varga for assistance in the construction and operation of the apparatus.

Quasars, Anti-matter and Optical Asymmetry

With reference to recent letters on quasars, anti-matter and optical asymmetry[1,2], it should be noted that Vester directed attention to the parallel between the asymmetry of matter and the optical asymmetry of metabolites, a few weeks after the discovery of parity non-conservation in weak interactions[3]. The relationship between asymmetry at the level of elementary particles and at the molecular level has been discussed in a number of publications[4-8]. In particular, the problem of the origin of optical activity in connexion with the origin of life has been considered, and it has been suggested that the optical asymmetry found on Earth is related to the structure of matter itself, that is, it is a reflexion of the asymmetry of our part of the Universe.

Rheological Behaviour of Granular Material

Instruments normally used for measuring viscosity are used from time to time for studying the flow properties of granular materials, especially rotational viscometers. Wieghardt[1] used, for sand, a large rotating cylindrical vessel, and measured the torque on a partly immersed long, smooth metal cylinder of small diameter. Benarie[2], working with powders, made use of an ordinary viscometer with a rotating bob, which had radially arranged baffles to avoid slippage. Kuno and Kurihara[3] in similar work used a MacMichael viscometer, rotating the outer cylinder, which also had baffles.

The aim of such investigations was to measure or compare the internal friction of granular materials, to eliminate wall-friction or slippage and to ensure a regular and well-controlled type of flow.

We carried out some experiments with a Rotavisko meter, using a special rotating body—a continuous helical screw—which conveyed the material upwards (Fig. 1). The screw was short-pitched, and had four pitches on a length of 6·2 cm. The speed of rotation could be varied over a very broad range—from 0·06 to 486 r.p.m. Readings of the torque were referred to in arbitrary units (one unit being 4·42 g cm). Smooth glass beakers of varying diameters were used as the containers, allowing an annular width of between 0·9 and 3·7 cm.

Our experiments were carried out on dry pearl barley—a roundish grain with dimensions of 0·16 × 0·25 × 0·27 cm and a kernel-weight of 6·7 mg. Some experiments were undertaken with a barley product in platelet shape (0·12 × 0·50 × 0·77 cm and a kernel-weight of 30·5 mg). Both materials could, for our purposes, be considered as free flowing and cohesionless. Due to the large size of the particles there was none of the complications associated with the formation of agglomerates, or with irregular and varying slippage planes in the mass of material, such as frequently occur in powders.

On rotating the screw in the granular mass, the particles could be seen to be taken up, to descend at the outer parts of the cylinder, to move inwards and to be picked up by the screw again, over the whole length—but for the most part in the upper half of the screw. The screw was filled largely, but not completely, with particles. The torque exercised on the rotating body would seem to be brought about largely by the friction between the ascending and the descending grains. At the centre, around the axis, a small bulge was observed. Compared with the static position, the surface rose 0·5–1·5 cm, depending on the speed of rotation. This rising indicates the dilatation which is necessary for the flow of a granular material. The movement of the grains was rather regular. With smaller annuli, or very high speed of rotation, turbulent eddies and slippage along the outer wall of the vessel were observed.

Readings were jerky, but this is not surprising for such large particles. The spread from moment to moment was larger with a small annulus, lower speeds and larger particle size. On the other hand, it could be reduced to ± 5–10 per cent when the annulus was large, the speeds high and the particles smaller. Ten or twenty readings were taken over a 5-min period, and the mean value calculated. Only a few minutes were required to reach the steady state. When rotation was interrupted and then resumed after some time, the same mean reading was obtained.

Apart from measurements taken when the screw was rotating, readings were taken after stopping it. Within a minute or so a constant value was found. This reading

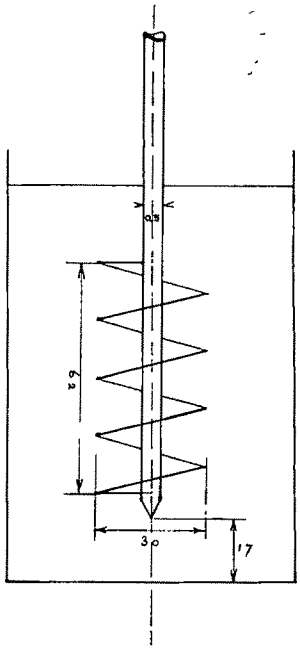

Fig. 1. Rotating screw

could be zero at very high speeds, 55–70 per cent of the rotating reading at average speeds, and frequently rose to 95 per cent for the lowest speeds of rotation. It could not, however, be taken as the true yield value of the granular material. On rotating, the mass was dilated and the packing density became lower than the static value. It took some time to settle and in this time the reading of the torque decreased to some extent.

The reading of the friction value was found to be independent of the speed of rotation. At 0·06 r.p.m. some irregularities were found; from 0·18 to 18 r.p.m. the reading barely increased (for larger annuli); but from 50 r.p.m. onwards larger values were found. The increase from 0·18 to 486 r.p.m., however, was not more than 1·5 fold. This can be explained by turbulent flow and eddying. It would seem that the internal friction, using the method described here, was largely independent of the velocity gradient—as would probably be so for any free-flowing granular material.

The influence of the width of the annulus was surprisingly small. With the round barley, annuli of 0·9–2·4–2·9–3·7 cm gave readings, at 6 r.p.m., of 9·5–7·8–8·3–8·6. At lower speed the difference was still smaller and at high speed it was somewhat larger. Even with the larger barley platelets the annuli of 2·4–2·9–3·7 cm did not have any great effect. The apparatus could thus also be kept within modest dimensions for larger particles.

The effect of the height to which the vessel is filled is given, for round barley, in Fig. 2. The reading of the torque has been plotted against $(\frac{1}{2}L + h)$, where L is the length of the screw (6·2 cm) and h the head above the screw. The friction was found, for the main, to be directly proportional to the pressure.

Comparing the two different types of barley, the smaller roundish and the larger platelet-shaped particles, we found torque (friction) readings of 7·9 and 8·7 respectively. Dividing by the loose bulk densities of 0·84 and 0·57 g/ml., we have calculated 'corrected' readings of 9·4 and 15·3. The platelets had a considerably higher internal friction coefficient. In these tests an annulus of 2·9 cm was used, and a head, $h = 0$; the mean readings at six speeds between 0·18 and 18 r.p.m. were calculated.

The addition of 3·0 and 5·7 per cent arachide oil to the round barley grains gave some cohesion to the particles. Under the same test conditions the friction readings dropped to 78 and 69 per cent respectively.

With the present instrument, it would be very difficult to calculate the friction coefficients in absolute units. It would be possible, however, to calibrate the apparatus by means of particles such as uniform glass spheres.

METALLURGY

Instrumented Impact Testing of Zircaloy

Coleman and Hardie's recent letter[1] on slow bend testing of hydrided zirconium poses some interesting questions with regard to the interpretation of the transition behaviour of zircaloy-2 (zirconium + 1·5 per cent tin) in impact tests. By instrumenting the Charpy machine to obtain the load/time relationship during fracture[2], the modes of brittle and ductile behaviour can be identified in a similar manner to slow bend testing. Using this technique, load/time curves have been obtained on hydrogen-free and hydrided (180 p.p.m. and 700 p.p.m.) zircaloy Charpy V specimens throughout the transition range.

Tracings of the load–time curves are shown in Fig. 1 together with the energy absorbed during the test. The energy transition of hydrogen-free zircaloy can be attributed to the rate of fall in load (corresponding to the advance of a crack through the specimen) which increases as the test temperature is lowered. This implies a change in ductility of the material at the root of the crack. At −196° C the load drop is extremely rapid, the crack presumably becoming self-propagating, as in Coleman and Hardie's work, due to the stored elastic energy in the specimen. At higher temperatures, continuous application of load is necessary to drive the crack through the specimen. The 'crack speeds' were calculated from the time interval between the point of maximum load and zero load, taking the maximum slope of the falling load–time trace, and are shown in Fig. 2. The 'crack speeds' for the self-propagating cracks possibly represent minimum values due to the limitation of the recording equipment.

The transition from slow crack growth to self-propagation occurs at much higher temperatures with the hydrided material. Within the transition range, curves similar to Coleman and Hardie's type *B* were obtained. It is considered that the load drop does not represent a general yield behaviour, but rather, at these large bend angles, the occurrence of a self-propagating crack down the centre of the specimen. The tail after the rapid load drop (250° C, 180 p.p.m.; 350° C, 700 p.p.m.) possibly repre-

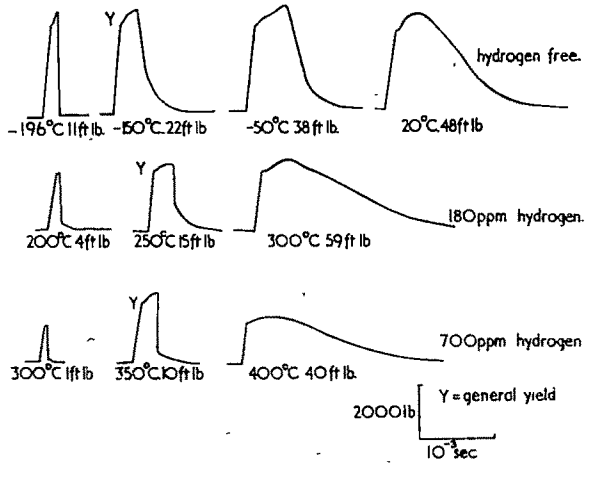

Fig. 1

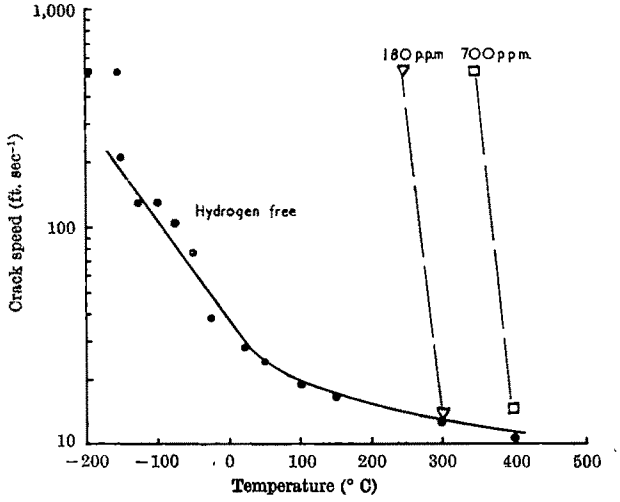

Fig. 2

sents the tearing of surface shear lips after the arrest of the rapid initial crack. The observation of this surface behaviour would possibly account for Coleman and Hardie's low value of the crack speed.

It is concluded that the wide transition in unhydrided zircaloy is due to a gradual decrease in ductility which facilitates easier ductile crack propagation. The intervention of rapid, self-propagating fractures in the hydrided material results in a much narrower transition range.

CHEMISTRY

Diffusion of Carbon Dioxide through Thin Layers of Solution

WE have adapted the Millipore filter principle of Scholander and Hemmingsen[1,2] to an extremely simple apparatus, and have used this to investigate the diffusion of carbon dioxide through buffer solutions with and without carbonic anhydrase. While the accuracy of absolute determinations of diffusion coefficient using this method is limited by uncertainty as to the thickness of the layer of fluid, the porosity of the Millipore filter, and the precise $[CO_2]$ gradient, it is clearly an adequate method for demonstrating large ratios of fluxes.

In order to measure the diffusion coefficient of carbon dioxide in aqueous solution it is customary to work at low *p*Hs to reduce the concentration of bicarbonate to a negligible amount[3]. At *p*H 7·4 the concentration of bicarbonate in equilibrium with dissolved carbon dioxide is twenty times the concentration of the latter and, as a consequence, in such a system the apparent diffusion coefficient of carbon dioxide should be increased by the concomitant diffusion of bicarbonate ion, which is reported to be as rapid as that of carbon dioxide[4]. It seemed possible that, during the rapid transit of carbon dioxide through the thin (0·015 cm) layer of solution in the Millipore filter, chemical equilibrium between dissolved carbon dioxide and HCO_3^- might not be established and the theoretical facilitation would not be realized. In the presence of excess carbonic anhydrase, however, chemical equilibrium should be closely approached and the apparent diffusion coefficient of carbon dioxide increased.

The diffusion cell of Mochizuki and Forster was used[5] (Fig. 1). Since carbon dioxide diffuses much faster than carbon monoxide, nitrogen or oxygen for the same partial pressure gradient the gas sampling technique previously used for measuring the flux of carbon monoxide could not be used. Instead a 0·1-ml. pipette containing a drop of paraffin oil was connected between the two chambers so that the movement of gas from one to the other with time could be followed. One chamber was filled with air, the other with expired gas (I. L.), which simplified the procedure and which varied less than several tenths of 1 per cent from the average value of 36 mm mercury when analysed on numerous occasions.

In this system the net flow of gas across the film is measured. However, the permeability of the film for carbon dioxide is about twenty times that for the other gases present, namely oxygen and nitrogen, owing to its greater solubility. The rate of exchange of these two gases will be only 4 per cent of the rate for carbon dioxide under the conditions in these experiments, and therefore we have neglected it.

In performing an experiment, the two chambers were filled with air and 5 per cent carbon dioxide mixture respectively with the stopcocks open to permit the pressures to equilibrate with atmospheric, the stopcocks then closed, and the time taken for the oil droplet to pass about eight successive 0·01 ml. divisions recorded. Since the total change in volume was 0·2 ml., this represents about 40 per cent of the process, and the back pressure cannot be ignored. It can be shown that the net change in volume (v) should be described by the following approximate equation:

$$v = 713 \frac{P_{A,0}}{\left[\frac{1}{V_A} + \frac{1}{V_B}\right]} \left(1 - \exp\left(-D\,713\left[\frac{1}{V_A} + \frac{1}{V_B}\right]t\right)\right) \quad (1)$$

$P_{A,0}$ is the partial pressure of carbon dioxide initially introduced into chamber A in mm mercury. 713 is the barometric pressure less the vapour pressure of water at 37° C, and considered constant. V_A and V_B are the volumes of the two chambers, which were 11·5 and 6 ml. respectively. The carbon dioxide was usually placed in the 11·5 ml. chamber. D is the transfer coefficient for carbon dioxide in the film in ml. (standard temperature pressure dry)/(min × mm mercury); t is the time in sec. The experimental results fitted this equation satisfactorily, so it was used to calculate D in conjunction with a semi-log plot. The equation is based on the simplifying assumption that the total gas volume of the chambers does not alter; however, this introduces an error of less than 3 per cent in the results. All experiments were performed at 37° C.

Pertinent results are summarized in Table 1. Although the absolute value of the apparent D is unreliable for the reasons already mentioned, its value in water is close to that extrapolated to 37° C from values reported in the literature[3] at 20° C, namely $2{\cdot}4 \times 10^{-5}$ cm²/sec, as is the value in N/100 hydrochloric acid. Attempts to take measurements at lower *p*H resulted in changes in the physical properties of the Millipore filter. There was no significant facilitation of carbon dioxide transfer in buffer at *p*H 7·9. However, on the addition of a fraction of a

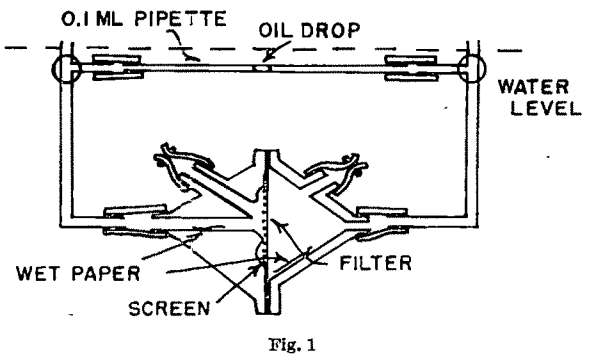

Fig. 1

Table 1. Apparent Diffusion Coefficient for Carbon Dioxide in Various Fluids

Fluid	No. of measurements	Apparent D (cm^2/sec)	$\pm S.E.$ mean (cm^2/sec)
Water	4	2.8×10^{-5}	$+0.16 \times 10^{-5}$
Water + $\frac{N}{100}$ HCl	3	3.1×10^{-5}	$\pm 0.47 \times 10^{-5}$
0·4 M Barbiturate buffer pH 7·9	9	3.2×10^{-5}	$\pm 0.15 \times 10^{-5}$
0·4 M Barbiturate buffer pH 7·9 + carbonic anhydrase	9	$*4.5 \times 10^{-5}$	$\pm 0.30 \times 10^{-5}$
0·4 M Barbiturate buffer + human blood	4	$*3.8 \times 10^{-5}$	$\pm 0.30 \times 10^{-5}$
Whole human blood: lysed	2	$*6.1 \times 10^{-5}$	—

* Probability that the value is greater than that for water is more than 95 per cent.

milligram of commercial carbonic anhydrase per ml., there was a 40 per cent increase in the apparent D (P less than 0·05). Addition of human blood, with its known carbonic anhydrase content, to the barbiturate buffer increased D, but not significantly. Facilitation was most marked in freeze-thawed whole human blood.

These observations are in line with A. V. Hill's comment on Krogh's estimations of the D_{CO_2} in tissue[6], which showed it was increased only 1·5 times over that in water. He suggested that the failure to find the twentyfold increase that would be expected on the basis of the $[HCO_3^-]$ gradient was due to the impermeability of cell membranes to the ion. However, ions cannot move in solution without the simultaneous movement of those of opposite charge in the same direction, or those of similar charge in the opposite direction. Thus in our system the bicarbonate ion could move across the membrane carrying with it the buffer cation, the $[H^+]$ being extremely small, which would set up a back gradient of buffer cation. Regardless of the identity of the ions that flow, the net effect would be to slow the overall process, which may be the explanation for the relatively small amount of facilitation found, about one-twentieth that expected from the experimental gradients of $[CO_2]$ and $[HCO_3^-]$.

The increase in apparent D_{CO_2} resulting from the addition of a miniscule amount of carbonic anhydrase to the buffer indicates that the hydration or hydrolysis of carbon dioxide is rate limiting in the absence of a catalyst. It is also pertinent that the diffusion of one weak electrolyte is decreased in the presence of others[7].

New Structure in the Electron Spin Resonance Spectrum of γ-irradiated Single Crystals of Ice

Electron spin resonance spectra obtained here for single crystals of ice, γ-irradiated and measured at 77° K, show structure not previously reported for the resonance near $g = 2$, which is generally assumed to be due to OH radicals. Earlier work by other authors has been directed mainly to the investigation of polycrystalline ice[1], except for a report[2] giving results on single crystals rather different from those reported here, and a recent communication[3] published near the end of these preliminary experiments.

The spectra obtained in the present work, which was at X-band, are in general complex and diffuse. However, the occurrence of quite sharp peaks for certain orientations of the crystalline axes with respect to the magnetic field, and also of a small, partly resolved splitting superimposed on the main OH doublet, suggests that the OH radical is at a normal oxygen site in the crystal lattice.

Single crystals from both ordinary water and heavy water (D_2O) were grown by the method of Adams and Lewis[4], and cylindrical samples were cut with their axes along the three symmetry axes of the crystal; these were then irradiated at 77° K with doses varying from one to ten Megarads in a cobalt-60 γ-source. Spectra were taken at 5° intervals for rotation about each of these axes, when arranged perpendicular to the applied field. Rotation about the c (unique) axis exhibited the expected six-fold symmetry with alternate mirror planes every 30°, while

Figs. 1–3. X-band spectra for single crystals of hexagonal ice, γ-irradiated and measured at 77° K. In each case the second derivative spectrum is shown with the absorption spectrum immediately below it. The calculated neighbour proton splitting is indicated under each absorption curve. The orientation of the magnetic field H with respect to the crystal c-axis and bond directions is also shown. For the doublet in Figs. 1 and 3, $g = (2.0207 \pm 0.0005)$, $A = (36.8 \pm 0.3)$ gauss. For the doublet in Fig. 2, $g = (2.0151 \pm 0.0005)$. $A = (34.3 \pm 0.3)$ gauss

on rotation about the other two axes each showed two mirror planes at right angles to one another[2].

Hexagonal ice has its oxygen atoms on a wurzite-type lattice, with one hydrogen atom to every bond. Each oxygen is surrounded tetrahedrally by four hydrogen bonds, with two of the hydrogen atoms bound covalently to it at a distance of 1 Å, and the other two loosely bound at a distance of 1·75 Å (ref. 5).

Three examples of second derivative spectra obtained are shown in Figs. 1–3, with the electronically integrated spectra below them. The bond symmetry for each orientation is shown to the right. Fig. 1 shows the spectrum obtained with the crystal *c*-axis parallel to the applied field, H. In Fig. 3 (*c*-axis at 70° to H). the bond co-ordination of Fig. 1 is repeated around half the oxygen sites, and part of the spectrum in Fig. 1 is seen to recur at half intensity. In Fig. 2 (*c*-axis at 55° to H), the tetragonal axis of the bonds for half the oxygen sites coincides with H, so that there are four bonds making equal angles of 55° with the field, and at this angle a sharp resonance is again observed. These results suggest that the various orientations have a symmetry very similar to that of the hydrogen bonding of the lattice—in contradiction to the model proposed by McMillan *et al.*[2]. It is thought possible that the radiation simply removes one hydrogen atom from the lattice. This would leave a hydroxyl radical either along one of the bond directions or, more probably, deflected from this direction towards the plane containing the three oxygen atoms to which the radical is still hydrogen bonded. Present analysis favours the latter model.

The small additional splittings observed are accounted for by a dipole–dipole interaction between the spin-electron and neighbouring protons. The result of a simple calculation in which it is assumed that the spin-electron is a point dipole at a normal oxygen site, with the two normal hydrogen-bonded protons at 1·75 Å distance, is shown under each spectrum. Transitions[6] of the form $\Delta m_I = 1$ were included in the calculation.

In the recent communication[3] reporting work on single crystals and powders of ice, it has been proposed that the low-field broad resonance (which clearly shows in the integrated spectrum of Fig. 2) is also due to the OH radical. Both annealing experiments and the angular variation of the D_2O spectrum observed in this laboratory tend to confirm this.

However, there is a small residual broad spectrum which remains when the OH resonance has been annealed, and this is also being investigated.

Oxidation of *Cyclo*hexane by Lead Tetra-acetate

Possibly because of displacement by apparently more attractive substrates, the reactions of lead tetra-acetate with simple paraffins has not received much attention. Earlier discussions[1,2] suggested that reaction in warm solvent was not likely although the promoting effect of paraffins on the thermal decomposition of the reagent in hot acetic acid had been noted[3]. Recently slow reaction with alkyl and aryl*cyclo*propanes has been reported[4].

*Cyclo*hexane has been used in photoreactions, for example, with nitrosyl chloride[5], ultimately resulting in large yields of *cyclo*hexanoneoxime as a result of the rearrangement of the initially formed nitroso compound indicative predominantly of mono-substitution, and with halogens[6], characterized by the appearance of poly-substituted products.

Contrary to the earlier suggestions, it has now been found that *cyclo*hexane reacts at a reasonable rate with lead tetra-acetate, giving good yields of a mixture of acetoxy derivatives. From the reaction of the paraffin (42 g; 0·5 M) with the oxidant (222 g; 0·5 M) in acetic acid (400 ml.) only 50 per cent of unchanged material was recovered from the thermal reaction at 80° (in the dark) and less than 40 per cent from the photoreaction (sunlight) at 20°–25° C. However, as shown in Table 1, there was a considerable difference in the distribution of products of the two reactions.

In the thermal reaction, the main bulk of products is divided between *cyclo*hexyl acetate and higher boiling material with comparatively little intermediate diacetates. This result suggests that initially formed monoacetate competes with unchanged hydrocarbon as a substrate for further oxidation.

By contrast, *cyclo*hexyl acetate appears as the main product of the photoreaction with markedly less higher boiling products, suggesting in turn that the hydrocarbon itself is the preferred substrate, that is, the tendency is to react preferentially with material of least degree of acetoxylation. This point was examined more directly by using *cyclo*hexyl acetate as initial substrate.

The acetate (71·2 g; 0·5 M) with lead tetra-acetate (222 g; 0·5 M) in acetic acid (400 ml.) was oxidized in a photoreaction. Products of the reaction, analysed as before, are indicated in Table 2.

The contrast with the thermal reaction in distribution of products is maintained. The total yield of diacetates is now far greater than that of higher boiling materials, which is again indicative of preferential attack on lower acetoxylated material—in this case the *cyclo*hexyl acetate. It seems likely that the build-up of higher acetates occurs mainly after the yield of diacetates has assumed competitive proportions.

A further point of specificity appears within the diacetate products. It is clear that much less attack occurs at the 2-position—the combined yields from the 3- and 4-positions giving a ratio of 13 : 1 with respect to distribution of products. This result can most probably be attributed to steric hindrance to attack at the 2-position.

In essence these results suggest that the thermal and photo-oxidations proceed by different mechanisms. The thermal reaction is subject to substituent influence, so that as acetoxylation proceeds the products tend to become the preferred substrates, thus yielding greater amounts of higher boiling materials without build-up of intermediate fractions to any great extent. It is very important, however, to note that this course of reaction only applies so long as unchanged *cyclo*hexane is present. An attempted thermal oxidation (80° C) of *cyclo*hexyl acetate in the dark showed no evidence of reaction even after a heating period

Table 1. Oxidation of *Cyclo*hexane (0 5 M) by Lead Tetra-acetate (0 5 M) in Acetic Acid

Oxidation product*	Thermal oxidation at 80° C (g)	Photo-oxidation at 20°–25° C (g)
*Cyclo*hexane not converted and methyl *cyclo*hexane formed	21 1	15·6
*Cyclo*hexyl acetate	8 5	16·95
Cis and *trans* 1,2-diacetates	1 9	1·5
1,3-diacetates	0·16	0 33
1,4-diacetates	0 28	0 37
Higher boiling acetates	10 0	3 9

* Analysis of neutral esters by gas chromatography using di-isodecyl-phthalate (20 per cent w/w) on 'Celite' as stationary phase, and helium (50 ml./min) as carrier gas. The column temperature was 170° C

Table 2. Photo-oxidation of *Cyclo*hexyl Acetate with Lead Tetra-acetate at 20°–25° C

Product	Yield (g)
Unconverted *cyclo*hexylacetate	44 7
Cis and *trans* 1,2-diacetates	1 3
1,3-diacetates	6·7
1,4-diacetates	9·6
Higher boiling acetates	8·3

of 170 h. Reaction was promoted by the addition of *cyclo*hexane.

The products of the photoreactions possibly result from an initial attack on the substrate by a methyl radical arising from the direct decomposition of the tetra-acetate[7]. Analysis of gas evolved during the photo-oxidation of *cyclo*hexyl acetate showed a methane/carbon dioxide ratio close to 1. The recovered hydrocarbon from the photoreaction of *cyclo*hexane included a small proportion of methyl *cyclo*hexane.

On the other hand, the mechanism of the thermal reaction is less obvious but must involve an association of paraffin, oxidant and ester. Work on this aspect is continuing.

Isolation of Ammonium Thiophosphite by means of Preparative Ion-exchange Chromatography

Although the existence of thio-derivatives of lower phosphorus anions has been accepted for some time, only one claim has been made of their isolation—by Lemoine[1,2] in 1881 and 1884. It now seems unlikely that his method of slow crystallization from a phosphorus sulphide hydrolysis mixture yielded single products, especially since he had no means of checking the purity.

A preliminary investigation showed that all of P_4S_3, P_4S_5, P_4S_7, and P_4S_{10} gave thiophosphorus species, in addition to simple phosphorus oxyanions when submitted to hydrolysis by solutions of sodium hydroxide or sulphide. Further investigation with anion-exchange columns coupled to a Technicon autoanalyser[3] established that one unidentified species was eluted just before monothiophosphate (PO_3S^{3-}) at *p*H 11·4 (see Fig. 1).

A linear gradient of increasing chloride concentration was used and comparison of the retention times of phosphite (HPO_3^{2-}) and phosphate (PO_4^{3-}) led to the prediction that this unknown anion was monothiophosphite (HPO_2S^{2-}).

Samples of this species were separated from the other phosphorus compounds by heavily overloading a large column (50 cm long, 3 cm diameter) of anion-exchange resin 'De-Acidite *FF*' and eluting with a constant strength of ammonium chloride buffered to *p*H 10 with ammonia. The resultant solution was evaporated down to a few millilitres at room temperature (20° C) under low vacuum and then adsorbed on to cellulose. Washing with a mixed solvent (42·5 isopropanol : 42·5 2-butanone : 15 conc. ammonia) removed the chloride, and the pure phosphorus salt was stripped off with ammoniated water. A white microcrystalline salt was precipitated from this solution with excess alcohol and the purity of the precipitated salt was checked using both thin-layer and anion-exchange chromatography.

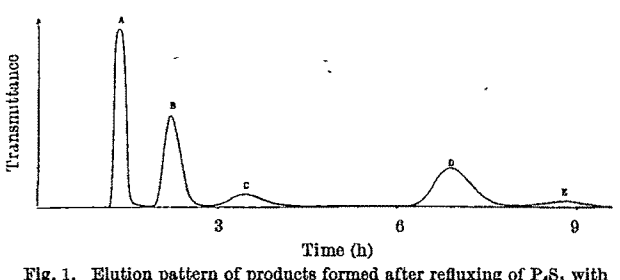

Fig. 1. Elution pattern of products formed after refluxing of P_4S_3 with excess 1 N sodium hydroxide for several minutes. *A*, Hypophosphite, *B*, phosphite; *C*, phosphate; *D*, unknown (monothiophosphite); *E*, monothiophosphate

The salt proved to be unstable towards water vapour, losing hydrogen sulphide in acid solution with the consequent formation of ammonium phosphite. Concentrated nitric acid and bromine water both react powerfully with the salt; a yellow solid is produced—presumably elemental sulphur. Its strong reducing properties are illustrated when silver nitrate is changed into the metal and a nickel spatula into black nickel sulphide.

A precursory examination of the infra-red spectrum reveals a sharp peak at 2,350 cm^{-1} which corresponds to the characteristic P—H stretching frequency. Weaker absorptions at 1,005 cm^{-1} and 415 cm^{-1} may be tentatively assigned to P—H deformation and P—S stretching vibrations respectively. A strong absorption due to the ammonium ion was seen at 1,415 cm^{-1}.

Analysis of the compound showed the phosphorus : sulphur : nitrogen ratio to be 1·00 : 1·01 : 2·03. For the empirical formula $(NH_4)_2HPO_2S$:

	P	S	N	H
Calculated	23·4	24·3	21·2	6·87
Found	22·7	23·8	20·8	7·01

The elution position under anion-exchange was sufficient evidence that there was one phosphorus atom per molecule. Moreover, the anhydrous nature was indicated when the salt decomposed on heating without melting, and no water was detected in the decomposition products

From the foregoing evidence the salt appears to be anhydrous diammonium monothiophosphite and its structure probably resembles that of trisodium monothiophosphate[4], that is:

$$[NH_4^+]_2 \quad \left[\begin{array}{c} H \\ | \\ S—P—O \\ \| \\ O \end{array} \right]^{2-}$$

Further investigations are in progress.

Synthesis of Alkyl-β-D-xylopyranosides in the Presence of Mercuric Salts

Synthesis of alkyl-β-D-glycosides has been achieved mainly through the reaction of poly-*O*-acetylglycosyl-halides with alcohols in the presence of a heavy metal (Koenigs-Knorr).

Except with simple alcohols, the most common procedure has been to dissolve the *O*-acetylglycosylbromide in an inert dry solvent, after adding a drying agent and silver oxide (dry and freshly prepared) and then adding an excess of the appropriate alcohol.

In recent years, mercuric salts have frequently been used. While there seems to be a general tendency for the reaction to proceed with Walden inversion, either anomer may be produced, depending largely on the aglycon concentration. Although the time of reaction is much shorter and a commercially available catalyst is used, mercuric

salts apparently are not widely used, and this is especially so for higher alcohols.

In the present work we prepared the tri-*O*-acetyl-alkyl-β-D-xylosides by condensation of tri-*O*-acetyl-α-D-xylopyranosylbromide with the appropriate alcohol (up to *n*-octanol) and used mercuric acetate as a catalyst. In each case the β-anomer was formed in good yield. Thus, even with higher alcohols, the more simple reaction with mercuric salts can be used.

The alkyl-β-D-xylosides were prepared by catalytic deacetylation of the corresponding acetates.

Preparation of the alkyl-tri-O-acetyl-β-D-xylosides. The tri-*O*-acetyl-α-D-xylopyranosylbromide was prepared by the method of Barczai-Martos and Körosy[1]. In the condensation reaction all the apparatus and reagents had to be thoroughly dry. The presence of water would have resulted in the production of a considerable amount of by-products, chiefly 2,3,4-tri-*O*-acetyl-D-xylose and a xylobiosacetate, tentatively identified as β-D-xylopyranosyl-β-D-xylopyranoside-hexa-acetate.

Acetyl groups were determined by the method of Kunz[2]. Mercuric acetate (16 g, 0·05 mol.), absolute chloroform (200 ml.), 'Sikkon' (18 g) and the appropriate alcohol (1–1·5 mol., except for heptanol and octanol, where 0·2 mol. was used) were stirred for 15 min at room temperature. During stirring, acetobromoxylose (33·9 g; 0·1 mol.) was added and the mixture refluxed on a water bath for 15 min. After cooling, the solution was filtered, thoroughly washed with water, dried, using sodium sulphate, and evaporated *in vacuo*. The resulting syrups were crystallized from the appropriate solvent.

The amyl-, hexyl-, heptyl- and octyl-xylosideacetates were purified by dissolving the final syrups in petroleum ether (b.p. 60°–80°), filtering of an insoluble residue (tri-acetylxylose and xylobioseacetate) and evaporating the filtrate *in vacuo*. The residue was dissolved in 95 per cent ethanol and kept at 4°. The products crystallized very slowly when water was added drop by drop over a period of several days.

Table 1 shows the alkyl-tri-*O*-acetyl-β-D-xylosides which were prepared in this way (all rotations were determined for chloroform solutions).

Preparation of alkyl-β-D-xylopyranosides. The xylosides were prepared by catalytic deacetylation with sodium-methoxide as described by Thompson and Wolfrom[3]. Table 2 shows the β-D-xylopyranosides which were prepared.

We thank Prof. L. Massart for his advice in this work.

Partial Specific Volumes of Solubilized Collagens and their Derived Gelatins

DETERMINATION of molecular weight by the method of sedimentation diffusion[1] necessarily involves the measurement of solute partial specific volume, $\bar{v}$. Owing to the highly viscous nature of solutions of soluble collagen, the determination of $\bar{v}$ for such materials is not easy. Previous investigators[2,3] have adopted a value of 0·70 ml/g for $\bar{v}$ of collagen; this is the value obtained for the much less viscous parent gelatin that is formed when collagen is denatured. It is thus implicitly assumed that there is no change in $\bar{v}$ on denaturation and we considered that this matter required experimental investigation. Accordingly, the normal pycnometric procedure for obtaining $\bar{v}$ has been utilized and found satisfactory for very dilute collagen solutions, despite the high viscosity. In 0·15 M citrate buffer, *p*H 3·67, at 20° C, typical values are:

calfskin acid soluble collagen, $\bar{v} = 0{\cdot}645 \pm 0{\cdot}010$ ml./g
calfskin soluble encollagen, $\bar{v} = 0{\cdot}625 \pm 0{\cdot}010$ ml./g
ossein soluble encollagen, $\bar{v} = 0{\cdot}650 \pm 0{\cdot}010$ ml./g

After thermal denaturation, the parent gelatin of acid soluble calfskin collagen gave $\bar{v} = 0{\cdot}695 \pm 0{\cdot}005$ ml./g at 40° C. This is in good agreement with the values previously obtained[2,3] for denatured ichthyocol and with the estimates computed from the amino-acid composition of gelatin[4,5] and the specific volumes of the component amino-acid residues[6].

The present results clearly demonstrate a significant change in $\bar{v}$ on denaturation of collagen, and the lower value in the undenatured state indicates not only a compact structure but also that strong intramolecular compressions must exist. At least a partial release of such compressions accompanies denaturation.

In the presence of 1 M sodium salicylate, a chemical denaturant, $\bar{v}$ for the calfskin parent gelatin is $0{\cdot}755 \pm 0{\cdot}010$ ml./g, a value much higher than that obtained by thermal denaturation. It is suggested that this result may reflect the release of highly compressed water from the protein by the binding of salicylate ions, though other mechanisms are not excluded. Rice *et al.*[7] have recently reported a small difference in $\bar{v}$ for calfskin collagen, according to whether the solvent is citrate or phosphate buffer. It would seem, therefore, that additional careful investigations of the variation of $\bar{v}$ with environment are required both for the highly compact collagen and for gelatin.

The introduction of the appropriate, new collagen values into the usual expression for molecular weight in terms of sedimentation and diffusion coefficients yields values some 17 per cent lower than previously obtained, in agreement with the indications of osmotic pressure work. By argu-

ments which will be presented fully elsewhere, the physicochemical investigations taken together tend to the view that a single (α −) chain of parent gelatin possesses a molecular weight of 90,000 ± 5,000.

BIOPHYSICS

Efficiency of Ion Transport Mechanisms

It has often been assumed, as in the theory of active transport of ions, that metabolic energy is required to transfer sodium ions from a low intracellular concentration to a higher concentration in blood serum or an external fluid[1–3]. On that assumption, the efficiency of any transport mechanism would be expressed as the ratio of output of work to input of energy. Theoretical calculations have been based on the following approximation, derived from the laws of ideal solutions:

$$\text{Ideal molal work} = RT \ln \frac{c_{Na}'}{c_{Na}''} \quad (1)$$

The work per unit time divided by the rate of energy conversion yields a value for the efficiency of the assumed mechanism. If the external concentration, c_{Na}', is 140 m.equiv./l. (as in blood serum), and if c_{Na}'' is taken as 28 m.equiv./l., then:

$$\text{Ideal molal work} = 1{\cdot}0 \text{ kcal per equivalent at } 37^\circ \text{ C} \quad (2)$$

If such an assumed process were to be continuous and irreversible, it would be accompanied by a large number of irreversible side-effects which do not appear to occur in Nature. The concentration of extracellular sodium would increase as intracellular sodium is depleted. There would be a simultaneous change in the electrolyte balance, which would be compensated only by a cyclical return of sodium ions from the higher concentration c_{Na}' to the cellular concentration c_{Na}''. To maintain a steady invariant state in cytoplasm and serum, it is necessary not only that c_{Na}' and c_{Na}'' remain constant, but also that the concentrations of chloride, potassium, and the other physiological ions remain fixed. A true calculation of the efficiency of any ion transport mechanism must consider the conditions of intracellular and extracellular invariance. For sodium the free energy change, ΔG, of the reversible isothermal process is zero:

$$\Delta G_1 = RT \ln \frac{c_{Na}'}{c_{Na}''} = (\Delta\mu_{Na})_1 \quad (3)$$

$$\Delta G_2 = RT \ln \frac{c_{Na}'}{c_{Na}''} = (\Delta\mu_{Na})_2 \quad (4)$$

$$\Delta G_{total} = (\Delta\mu_{Na})_1 + (\Delta\mu_{Na})_2 = 0 \quad (5)$$

where $\Delta\mu_{Na}$ is the change of chemical potential of sodium ions.

Similar considerations apply to the other ions. Equations (1)-(5) are based on the ideal solution laws, often assumed to be approximately valid for cells and tissues. In a generalized formulation, non-ideal terms are required[4–6]. According to the theory of electrolyte solutions, the chemical potential, μ_i, of any ion is defined by the equation:

$$\mu_i = \mu_i^0 + RT \ln c_i f_i \quad (6)$$

where μ_i^0 is the standard chemical potential and f_i is the activity coefficient. By an appropriate definition of the standard state of a physiological system, the activity coefficient of any ion may be assigned the value 1·0, and the non-ideal deviations may be expressed by a change of μ_i^0 between two different phases. Thus the change of chemical potential, $\Delta\mu_{Na}$, between blood serum and cytoplasm is given by:

$$\Delta\mu_{Na} = \Delta\mu_{Na}^0 + RT \ln \frac{c_{Na}''}{c_{Na}'} \quad (7)$$

This may be expressed in the following way:

Real molal work = non-ideal molal work + ideal molal work

The magnitude of $\Delta\mu_{Na}^0$ is of the order of 2·3 kcal, or −100 mV in electrical units[5,6]. If the ideal molal work is −1·0 kcal (equation (2)), then the real value of $\Delta\mu_{Na}$ is 1·3 kcal, or −56 mV. The value is of the same order of magnitude as the ideal molal work, but of opposite sign. Therefore, when account is taken of the 'non-ideal work', there is no need of a hypothetical pump to force sodium ions up a 'concentration gradient'. Its place is taken by $\Delta\mu_{Na}^0$, the value of which depends only on non-ideal deviations from the ideal equation of state.

Over any closed cyclic process in an invariant system, $\Delta\mu_{Na}$ is zero (equation (5)). The conditions of invariance require c_{Na}' and c_{Na}'' to remain constant. The constant $\Delta\mu_{Na}^0$ depends only on the nature of the two phases, and is independent of intermediate steps or mechanisms. The condition of invariance requires that the integral of $d\mu_i$ for any ion over any pathway C depends only on the initial and final states. The value becomes zero over any path in which the initial and final states are the same. These conditions are expressed by equations (8–10).

$$\int_C d\mu_i = 0 \quad (8)$$

$$\int_C d\mu_i^0 = 0 \quad (9)$$

$$\int_C RT \, d \ln c_i = 0 \quad (10)$$

All other thermodynamic functions, such as entropy, free energy and enthalpy, have the same property: they depend only on the physicochemical state of any phase, and are independent of the paths of transport processes.

In any physicochemical system at constant temperature and pressure, the condition of invariance requires that ΔG be zero for all possible redistributions of ions. Spontaneous processes can occur only in the direction in which ΔG is negative. We have shown[4–6] that the conditions for maximal stability in a heterogeneous system are:

$$\Delta\mu_{Na} = \Delta\mu_K = \tfrac{1}{2}\Delta\mu_{Ca} = \tfrac{1}{2}\Delta\mu_{Mg} = -\Delta\mu_{Cl} \quad (11)$$

The most stable distribution is determined by the value of $\Delta\mu^0$ for each ion.

In general, the maximal work, w_{max}, is equal to the decrease of free energy. Thus:

$$\Delta G = -w_{max} \quad (12)$$

For an ideal gas:

$$\Delta G = RT \ln \frac{p_2}{p_1} \quad (13)$$

A gas pump requires a supply of energy to transport air from a low pressure, p_1, to a high pressure, p_2. However, if the air simultaneously returns to the lower pressure, ΔG is zero, and no effective work is performed. The efficiency is zero. In the atmosphere there is a pressure gradient with increasing altitude, but this cannot be converted to

useful work. The condition of maximal stability requires that ΔG be zero between any two altitudes or pressures. Air may freely circulate between any two levels with no change of free energy or performance of work.

If there is a sodium pump or other ion transport mechanism within cells, operating to perform work by increasing the free energy or chemical potential of the ions, then its maximal efficiency must be zero. The reason for this is that it operates in an invariant, isothermal, heterogeneous system. The condition for invariance requires, among other things, that an equivalent quantity of ions must immediately return to the cells. The values of ΔG and $\Delta\mu$ over any cyclical isothermal process in an invariant system may readily be shown to be zero, since they depend on only one fixed state. According to Carnot's principle, the reversible isothermal work is zero. Therefore, the efficiency of any energy-consuming mechanism operating in the reversible cycle must also be zero. Efficiency can be measured only for work-producing processes, such as muscular contraction, which involve both reversible and irreversible steps.

If there is no sodium pump, it is meaningless to calculate its efficiency.

BIOCHEMISTRY

Structure of α-Keratin

IN a recent publication, Fraser, MacRae and Miller[1] have given a comprehensive interpretation of the X-ray diffraction photograph of α-keratin (porcupine quill tip) and, in particular, considered the quantitative aspects of the small-angle and large-angle equatorial scatter. This problem has also been discussed by Wilson[2], whose approach differs in some important respects from that of Fraser *et al.*, although based on a microfibril model of the same type. Wilson supposes that interference effects between protofibrils within a microfibril, as well as between different microfibrils, affect the X-ray intensity at small scattering angles, whereas Fraser *et al.* consider only the 'between microfibril' interference. According to them, the small-angle scatter can be ascribed solely to a difference in effective mean electron density between the microfibrils and their surrounding matrix, and for a given microfibril-matrix texture the intensity should be simply proportional to this difference. The evidence in favour of this idea is that when heavy metals, such as silver or osmium, are incorporated in the matrix material the main effect on the diffraction is to enhance the small-angle scatter, leaving the maxima of intensity at the same scattering angles as before.

On physical grounds, Wilson's theory is inadequate[3] if only because of his neglect of the side-chain scatter. Fraser *et al.* consider the side-chain scatter, but assume that it completely annuls the protofibril scatter at small angles. We believe that the truth lies somewhere between these extremes, and that the effect of the side-chains and other material between the protofibril main-chains must be to reduce, but not to eliminate, the protofibril intensity at small angles.

This belief is strengthened by our experimental results for the equatorial scatter of Lincoln wool. In a general way these are similar to those quoted by Fraser *et al.* for porcupine quill, with one important exception. This is that the relative intensities of the 45 Å and 27 Å reflexions are quite different in untreated and metal-containing wool (the intensities are roughly equal in untreated fibres, but the 45 Å reflexion is some five times stronger than the other in the silver-wool). The intensity contour, therefore, cannot depend on the relative electron densities of the matrix and microfibril in the way which Fraser *et al.* suppose; some other factor, presumably associated with the arrangement of the protofibrils in the microfibril, must modify the intensity at small angles in untreated wool.

We have examined this possibility in its quantitative implications, and have evolved a model structure which seems to have the correct scattering properties. In this, the microfibril consists of an annular array of protofibrils surrounding a core. The protofibrils have organized and less organized regions along their lengths, the former having diffraction properties like Crick triplet coiled-coils. A maximum of nine such protofibrils could be fitted into the annulus, but they need not all be organized into coiled-coils in any particular cross-section of the microfibril; we suppose, therefore, that there is an effective average number f_a (less than 9) of coiled-coils in the annulus. The microfibril core might also show coiled-coil organization and we suppose that it scatters X-rays as if it contained f_c (less than 2) coiled-coils in the cross-section. The unorganized material in the microfibril is taken to scatter like a uniform electron cloud filling the gaps between, and to some extent within, the coiled-coils. A similar cloud between the microfibrils simulates the scatter from the matrix. The small-angle scatter of such a model consists of (*a*) a part due to microfibril-matrix texture, of the type envisaged by Fraser *et al.*, and (*b*) a part due to protofibril scatter modified by interference between protofibrils in the same microfibril. Both components have maxima near 45 Å and 27 Å; in (*a*) the former is more intense, in (*b*) the latter (to an extent depending on the ratio f_c/f_a). In untreated Lincoln wool component (*a*) must be small (the mean electron densities in the matrix and microfibril being approximately equal) so that the small-angle scatter is mainly due to (*b*). In silver-stained wool only (*a*) is important (electron density of stained matrix being large). In other keratin fibres it may happen that both (*a*) and (*b*) contribute significantly, to give an intermediate type of intensity contour.

Incorporation of Labelled Lysine into the Desmosine Cross-bridges in Elastin

THE isolation and chemical characterization of two new amino-acids, desmosine and isodesmosine, which form bridge-points between peptide chains in elastin has already been described[1–3]. The isomeric compounds are 1,3,4,5- and 1,2,3,5-tetra-substituted pyridinium salts with the empirical formula $C_{24}H_{40}N_5O_8Cl$ (as the chloride). Consideration of the structure of the two compounds and their location as cross-bridges between peptide chains led Partridge *et al.*[4] to suggest a possible biosynthetic route through ring closure on four lysine residues pre-existing in the peptide chains of a soluble pro-elastin.

A preliminary attempt to verify this suggestion experimentally has already been reported[5]. In these experiments groups of rats, 25 days old, were injected at intervals for 9 days with U-^{14}C-lysine and the animals were killed 12 h after the last injection. Lysine, desmosine and isodesmosine were isolated from purified elastin prepared from the aortae. The results showed that under the conditions of the experiments about 2 moles of lysine, instead of the expected 4 moles, were incorporated into each mole of desmosine and isodesmosine; it was remarked that this unexpectedly low result could have arisen because of a time lag between the incorporation of labelled lysine and ring-closure to form the desmosines.

About the same time a publication by Miller, Martin and Piez[6] showed clearly that the elastin from the aortae of 12-day-old chick embryos contained much more lysine and less desmosine and isodesmosine than elastin from full-grown birds. Over the age-range investigated the sum of lysine and quarter-desmosine remained constant and there was a smooth transition of the lysine/quarter-desmosine ratio with increase in age. The same authors reported that, in tissue culture experiments with chick embryo aorta, the amount of lysine incorporated into desmosine and isodesmosine increased steadily for some days after the culture had been allowed to take up a quantity of radioactive lysine from the medium. When the aortae were allowed to grow in a medium without labelled lysine for 11 days after a pulse dose of U-^{14}C-lysine, the specific activity of desmosine and isodesmosine was a little more than four times that of the lysine isolated from the same sample of elastin.

The experiments now reported confirm our tentative conclusions from the preliminary experiments[5] and show that the results of Miller *et al.*[6], obtained with avian embryo aorta in tissue culture, are valid for the growing rat.

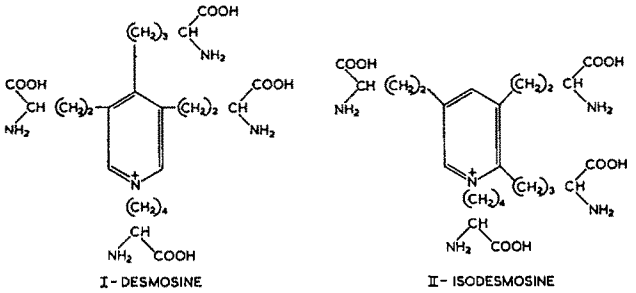

Fig. 1

The experimental procedure adopted was similar to that described earlier[5] except that after receipt of a concentrated pulse dose of U-^{14}C-lysine the groups of animals were fed a normal growth ration *ad lib.* until they were killed. Three groups of ten weanling male Sprague–Dawley rats were each kept for 8 days under the conditions of the experiment before the injections were started. Each rat received a total of approximately 0·030 mc. of U-^{14}C-lysine given in three doses per day for 10 days. The groups were killed 0·5 days, 5 days and 17 days after the last injection. The aortae were dissected from the aortic valve to the bifurcation; they were then freed from connective tissue and washed exhaustively with 0·15 M sodium chloride and dehydrated with acetone. The dried defatted aorta powder was treated with 0·1 N sodium hydroxide at 98° for 45 min[7], washed six times with hot water, and dried by treatment with ethanol and ether. The purified elastin was hydrolysed by refluxing with iron-free 6 N hydrochloric acid for 72 h in a current of nitrogen; desmosine, isodesmosine and lysine were isolated chromatographically as already described[5]. Samples (1·0 ml.) were taken from the centre fraction of each peak for scintillation counting in Bray's solution (21 ml.) containing 'Thixcin' (25 g/l.). A second sample (0·5 ml.) from the same fraction was used for the estimation of the amino-acid concentration using the Technicon 'Auto-analyser'. The results are given in Table 1.

Table 1. Incorporation of U-^{14}C-lysine into Desmosine and Isodesmosine

Sample	Days after last injection	c.p.m.	μmoles amino-acid	c.p.m./μmole	c.p.m./μmole ratio to lysine
(1)	0·5 days				
	Isodesmosine	40·8	0·062	660	1·57
	Desmosine	45·9	0·080	573	1·36
	Lysine	176·2	0·418	421	1
(3)	5 days				
	Isodesmosine	91·7	0·079	1,150	3·0
	Desmosine	83·2	0·085	977	2·6
	Lysine	199·0	0·527	377	1
(4)	17 days				
	Isodesmosine	108·5	0·113	958	4·56
	Desmosine	113·0	0·125	905	4·30
	Lysine	76·7	0·366	210	1

It will be observed that the molar specific activity of the desmosine isomers increased with time after the pulse dose of U-^{14}C-lysine and eventually reached a value of rather more than four times that of the lysine isolated from the same sample of elastin. That the figure was fractionally in excess of four was to be expected since there was considerable growth of aorta tissue during the 17 days which elapsed before the animals were killed. Since elastin from young animals contains a higher lysine/desmosine ratio[6], the activity of lysine is diluted to a greater extent relatively to the desmosine isomers. The results also show that the activity of isodesmosine was significantly higher than that of desmosine throughout the duration of the experiment. This may result from a difference in the rate of formation of the isomers and from the circumstance that mammalian elastin contains more desmosine than isodesmosine.

The incorporation of four molecules of lysine into both desmosine and isodesmosine, and the demonstration that the cyclization process is a slow one occupying up to 17 days after the uptake of the lysine, provides an adequate explanation for the observed variation in the composition and physical properties of elastin from animals at different stages of growth. However, it does not preclude the possibility that residues other than lysine may be involved in cross-bridges.

Chemical investigation of the structure of the isomeric desmosines[2,3] has resulted in the location of all the carbon atoms except for the methylene groups in the side chains on positions 3, 4, 5 in desmosine and 2, 3, 5 in isodesmosine. The demonstration of the biosynthesis of the desmosines from four lysine residues shows that the isomers arise by cyclization of straight-chain 6-carbon units and indicates (I) and (II) as the probable structures of the isomers.

Inhibition of the Biosynthesis of the Cross-links in Elastin by a Lathyrogen

In some animal species nutritional deficiency of copper is known to result in a defect of the walls of the large arteries which leads to aortic rupture[1,2]. The defect has been attributed, at least in part, to a change in the amino-acid composition of elastin[3,4]. The lysine content of elastin isolated from copper-deficient animals is abnormally high, and there is reason to believe that this is related to a failure in the biosynthesis of linkages connecting the peptide chains.

Recently two new amino-acid isomers, desmosine and isodesmosine, have been isolated from hydrolysates of elastin and characterized as tetra-amino-tetracarboxylic acids containing quaternary pyridinium rings[5,6]. These substances appear to be in peptide linkage with at least two primary chains and thus can act as cross-links. The empirical formula of the isomeric desmosines, $C_{24}H_{39}N_5O_8$, suggested that they might arise biosynthetically by the oxidation and cyclization of four lysine side chains[7] and this was confirmed by feeding experiments with U-^{14}C-lysine[8,9]. Using chick embryo aorta in tissue culture, Miller, Martin and Piez[10] showed that added U-^{14}C-lysine is incorporated into the desmosines *in vitro* and that the molar ratio of the specific activities of the desmosines and lysine reached 4 : 1 about 11 days after the addition of a pulse dose of labelled lysine.

The symptoms of copper deficiency and lathyrism in turkey poults are highly analogous[11] and unpublished observations[12] have shown a decreased content of elastin in the aortae removed from poults fed β-aminopropionitrile (BAPN). Chick embryo heart tissue grown in organ culture produces extra-cellular fibres which give tinctorial reactions typical of elastin, and these fibres are reduced in amount in cultures which contain BAPN[14]. In the present experiments, some of which have already been briefly reported[13], the amino-acid composition of elastin from BAPN-fed chicks has been determined and the effect of BAPN on desmosine formation in aorta grown in organ culture has been investigated.

Two groups of chicks were fed a commercial chick meal for one week. Then 0·05 per cent of BAPN (3-amino-propionitrile fumarate, Aldrich Chemical Co., Milwaukee, Wisconsin) was added to the diet of one group and the feeding continued for 2 weeks. At 3 weeks of age the aortae were removed, cleaned of blood and adhering tissues and ground in a glass homogenizer in 0·9 per cent saline. The insoluble portion was dehydrated with acetone, washed with diethyl ether, and dried. Sufficient water was added to rehydrate the powder and 0·2 ml. of 90 per cent formic acid per mg of dry tissue was added. The suspension was held at 45° C for 36 h (ref. 15), then washed thoroughly with water and finally with acetone and ether. The amino-acid composition was determined by use of a Technicon 'Autoanalyser' after hydrolysis in 6 N hydrochloric acid under reflux for 72 h. For purposes of comparison, elastin prepared by 0·1 N sodium hydroxide treatment of aortae from copper-deficient and control chicks was similarly analysed (we thank Dr. J. E. Savage and Mr. D. Bird, University of Missouri, for the preparation of this material). Without correction for losses during hydrolysis, approximately 91 per cent of the nitrogen in the 'control' elastin and 96 per cent of that in the 'BAPN-fed' elastin was recovered. There was essentially no difference in the amino-acid composition of the experimental and control elastins except for lysine and the desmosines. The results are shown in Table 1. In the case of the copper-deficient elastin, the lysine content was nearly five times that of the control, while the desmosines averaged only 60 per cent of the control values. The 'BAPN-fed' elastin showed no change in desmosine and had only twice the normal lysine content. The failure to observe more significant differences was doubtlessly due to the mild nature of the lathyrism induced. Mortality was low and no gross abnormalities of the aorta were observed.

For investigations of organ cultures, aortae were removed from young ducklings, 1–7 days of age, under aseptic conditions, and placed in roller tubes containing tissue culture medium 199 supplemented with 25 units each of penicillin and streptomycin per ml. One half of the tubes contained 5 × 10^{-3} M BAPN and all contained 0·1–0·75 μc. of [U-^{14}C]-lysine per ml. during the first 2 days of culture. The cultures were then supplied with medium without labelled lysine and continued for 10–14 days with renewal of medium on alternate days. The cultures were collected, washed, dehydrated with acetone and, finally, washed with ether. Elastin was isolated by heating in 0·1 N sodium hydroxide for 1 h in a boiling water bath and repeated washing with hot water. Lysine, desmosine and isodesmosine were isolated and their specific activities determined as previously described[8]. Table 2 shows that the specific activity of the lysine isolated from the elastin was directly proportional to the concentration of the labelled lysine in the culture medium. The presence of BAPN slightly increased the specific activity of lysine, but in each experiment the specific activities of desmosine and isodesmosine were depressed to about one-tenth or less of the value found for the controls.

The results now obtained show that, as in copper deficiency, the presence of the lathyrogen results in the formation of an elastin with a high lysine content. The organ culture experiments demonstrate that BAPN inhibits the incorporation of lysine into the desmosine cross-linkages. Since the amino-acid analyses shown in Table 1 were performed on elastin which remained insoluble after extraction with hot alkali or concentrated formic acid it seems reasonable to suppose that the elastin isolated was at least partly cross-linked, and a marked fall in the content of desmosine and isodesmosine was not to be expected. However, with lathyritic elastin, as with that resulting from copper deficiency, the sum of lysine plus quarter-desmosine is markedly greater than is found with normal elastin, either from young or old animals. It is therefore apparent that there is an intermediate in desmosine synthesis which is destroyed by acid hydrolysis or has not yet been found in the hydrolysis products.

The analogy between the effects of BAPN and copper deficiency on the chemical and physical properties of elastin suggests that an enzyme system concerned in the condensation of lysine side-chains to desmosine requires

Table 1. Effect of Copper Deficiency and BAPN Feeding on the Composition of Purified Chick Aorta Elastin

Sample	Control (1)	Copper-deficient (1)	Control (2)	BAPN-fed (2)

copper and that BAPN inhibits at least one step in the reaction chain. Although collagen and elastin have very different compositions and structure, it is of interest to note the apparent parallelism displayed in the effect of BAPN on the processes by which primary peptide chains are organized into a coherent fabric.

Rate of Protein Biosynthesis in Hepatoma 223

Hepatoma 223, unlike the liver of an adult rat, rapidly increases its protein content. It might, therefore, be expected that its protein-synthesizing activity would be greater than that of liver so the efficiency of the *in vitro* systems from the two tissues were compared.

The cell sap and ribosome fractions of liver were obtained by methods previously described[1]. The cell sap was passed through a column of 'Sephadex *G*-25' equilibrated with medium *B* (48 mM sodium chloride, 100 mM potassium chloride, 10 mM magnesium chloride and 50 mM Trizma buffer, *p*H 7·6) to remove low molecular weight inhibitory substances[2]. The ribosomes and cell sap of the tumour were isolated by an essentially similar procedure. Ribosomes and excess of the cell sap fraction were incubated together in medium *B* containing 5 mM adenosine triphosphate, 0·05 mM guanosine triphosphate, 10 μg/ml. of an amino-acid mixture (lacking leucine) and 0·1 μc./ml. DL-[1-^{14}C] leucine. The reaction was stopped by addition of 0·5 N perchloric acid and the proteins isolated and prepared for counting as previously described[1].

It was found in a number of cross-over experiments in which ribosomes of tumour were incubated with tumour or liver sap that the efficiency of the ribosomal fraction of the tumour did not differ significantly from that of liver (96 per cent ± 8 per cent). It was found that the efficiency of the cell sap fractions from the two tissues were also very similar provided that their concentrations were not limiting.

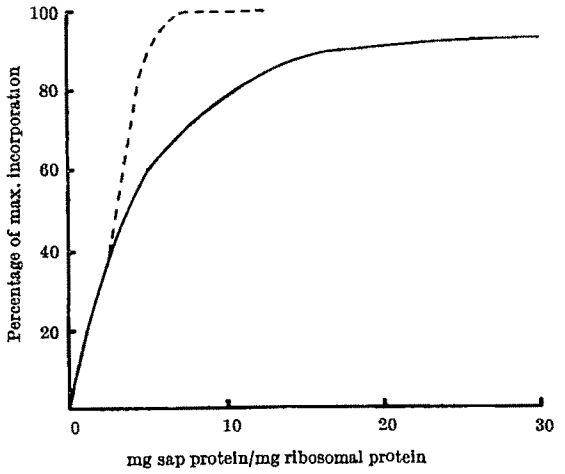

Fig. 1. The dependence of the incorporation of amino-acids into protein by the cell-free system, on the concentration of cell sap protein. The conditions of incubation are given in the text. 100 per cent represents about 3,000–5,000 c.p.m./mg ribosomal protein. —, Liver, . . . , tumour

The extent of amino-acid incorporation into protein in the ribosome cell-free system is, however, greatly affected by the amount of cell sap protein added (Fig. 1). It will be seen that, in the case of liver, a ratio of about 20 : 1 of cell sap protein to ribosomal protein is needed to ensure that enough sap constituents are present. It is also clear that the tumour cell sap saturates at a lower protein concentration than does that of liver. For example, the amount of protein required to give 80 per cent saturation in the liver system is about 3·5 times as much as in the tumour system. The higher efficiency of the cell sap protein from the tumour seems to reflect a higher concentration of soluble components of the protein synthesizing mechanism relative to other proteins in the cell sap fraction. We have noted, for example, that the tumour sap contains twice as much *s*RNA as liver sap per gram wet weight of tissue (that is, four times as much *s*RNA per mg cell sap protein) and this may account for the difference.

Table 1. Composition of Tumour and Liver (mg/g Wet Weight Tissue)

	Liver	Tumour
RNA	11	6·3
Protein	225	110
Ribosomes	13	7 5
Soluble fraction	90	44

RNA was estimated by the method described in ref. 1.
For the calculation of the quantity of ribosomes it is assumed that 50 per cent of the RNA of the cell is associated with ribosomes (ref. 3) and that they are 42 per cent RNA. It was also assumed that the amount of soluble fraction protein is 40 per cent of the protein of the whole tissue (ref. 3).

Table 1 shows the experimentally determined RNA and protein contents of liver and tumour and the calculated concentrations of ribosomes and cell sap. The tumour contains about half the ribosomal and cell sap content of liver (per g of tissue). The cell sap of tumour is several times as active as that of liver so it appears to be unlikely that cell sap activity is rate limiting. Since the tumour has half the number of ribosomes of liver and each has about the same activity as those of liver, the rate of protein synthesis of the tumour must be about half that of liver. Nevertheless, the tumour accumulates protein. This must arise because of some mechanism other than an increased rate of protein synthesis. It could be explained by differences between liver and tumour in the proportion of the protein produced which is retained by the tissue, or by differences in the type and stability of proteins made, and by other factors.

Presence of Sodium–Potassium-stimulated ATPase in Boar Epididymal Spermatozoon

SINCE Skou[1] reported that an adenosine triphosphatase (ATPase) stimulated by sodium and potassium in the presence of magnesium (Na–K ATPase) is present in submicroscopic fraction of crab nerve, many investigators have reported the presence of the same ATPase in various tissues[2–6] (see also Hokin and Hokin's recent review[7]), and it was suggested that it plays an important part in the process of active transport of potassium and sodium ions. However, information concerning the presence of such an ATPase in spermatozoa is not, as yet, available. It seems very likely that active ion transport mechanism is also present in the spermatozoon, as its motility is affected by ionic environment. This communication reports our detection of Na–K ATPase activity in boar epididymal spermatozoon.

Spermatozoa obtained from fresh epididymal tissues of a boar were washed twice in 0·25 M sucrose solution and re-suspended in a 0·25 M sucrose solution containing 35 mM *tris*-hydrochloric acid buffer (*p*H 7·4). ATP was rendered free of sodium and potassium by passing it through a 'Dowex 50' cation-exchange resin column in the hydrogen form. The free acid was brought to *p*H 6·8 with 1 M *tris* solution. The reaction mixture contained 3 mM ATP, 3 mM magnesium ions, 35 mM *tris*-HCl buffer (*p*H 7·4) and various concentrations of sodium and potassium ions. Ouabain was added to the medium as required. The total volume of the reaction mixture was kept constant at 2·0 ml. After incubation for 30 min at 37° C, the reaction was stopped by the addition of 1 ml. of 30 per cent trichloroacetic acid, and liberated inorganic phosphorus (P_i) was determined by the method of Fiske and SubbaRow. Activity was expressed as μmoles of inorganic phosphorus/10^{10} sperm/h. The ATPase activity of intact spermatozoa is shown in Fig. 1.

As shown in Fig. 1, ATPase activity of intact spermatozoa increased in the presence of 3 mM of magnesium, and it was stimulated further by sodium ions but not by potassium ions alone. The activity was greatly enhanced by the addition of both sodium and potassium ions in the presence of magnesium ions. Fig. 1 shows also that the ATPase activity in the complete system is inhibited by the addition of 5×10^{-4} M ouabain. The presence of such an ATPase activity in intact spermatozoa suggests that spermatozoa may have a function of active transport of potassium and sodium ions. The following experiments were undertaken to investigate the distribution of Na–K ATPase activity in the spermatozoa.

Washed spermatozoa were suspended in 0·25 M sucrose solution containing 0·2 per cent sodium deoxycholate, 5 mM EDTA, 30 mM histidine–HCl, 30 mM 2-amino-2-methyl-1,3-propanediol, at *p*H 7·0, and subjected to ultrasonic treatment at 10 kc/s for 5 min. The sonicate was homogenized using a 'Teflon' pestle-glass homogenizer at 1,000 r.p.m. for 3 min, and the homogenized sonicate was fractionated by differential centrifugation into four fractions, namely, head, tail, Fraction 1 (which was collected by centrifugation of the supernatant at 10,000*g* for 10 min) and Fraction 2 (which was collected by centrifugation of the supernatant of Fraction 1 at 105,000*g* for 60 min). Each fraction was washed twice in 0·25 M sucrose solution and tested for the Na–K ATPase activity. Typical results of an experiment are shown in Table 1.

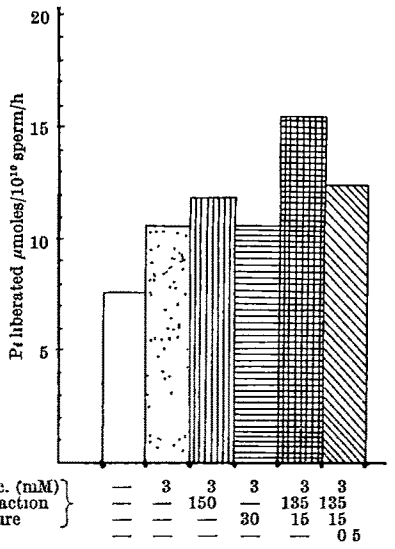

Fig. 1. ATPase activity of intact boar epididymal spermatozoa. The incubation medium consisted of 3 mM ATP, various cations as described above, and 35 mM *tris*-HCl buffer (*p*H 7·4)

Table 1 ATPASE ACTIVITY OF FRAGMENTED BOAR EPIDIDYMAL SPERMATOZOON

Fragmented spermatozoon	Activity (P_i, μmoles/N mg/h) Mg	Mg+Na+K	Mg+Na+K/Mg
Head	2·07	2 12	1·02
Tail	17·72	18·90	1·07
Fraction 1	5·53	6 90	1·25
Fraction 2	6·68	8·70	1 30

The incubation medium consisted of 3 mM ATP, 3 mM magnesium chloride, 105 mM sodium chloride, 30 mM potassium chloride, 35 mM *tris*-HCl buffer (*p*H 7·4). The enzyme suspension was added after 5 min temperature equilibration at 30° C, and incubation was continued for a further 30 min. The reaction was stopped by the addition of 1 ml. of cold 30 per cent trichloroacetic acid and aliquots were assayed for inorganic phosphate by the method of Fiske and SubbaRow.

It will be seen from these results that in the presence of magnesium alone ATPase was highest in the tail—which agrees with the results obtained by Nelson[8] for fragmented bull spermatozoa. On the other hand, Na–K ATPase activity was highest in Fraction 2, which contains microsomal sediment, and rather low in other fractions. In other experiments, Na–K ATPase activity of Fraction 2 was inhibited by addition of 10^{-5} M ouabain. Consequently it seems likely that Na–K ATPase activity in intact spermatozoon did not originate from the tail fraction, which consists of a myosine-like substance, but chiefly from Fractions 1 and 2, namely, membranes, mitochondrial and microsomal fractions. It is probable that this sodium–potassium-activated ATPase plays an important part in the enzymatic mechanism of active ion transport involved in the excitation and movement of the spermatozoon.

Sub-cellular Distribution of Serotonin in the Developing Rat Brain

It is well known that the neonatal rat brain contains relatively little serotonin[1,2] and that the level of this amine increases slowly with age. Karki *et al.*[3] have shown that the enzymes mediating the synthesis and oxidation of serotonin are also low in the immature rat brain, and increase thereafter with growth of the animal. The aforementioned authors suggest that the low levels of indolamines in the rat brain at birth can be attributed to a deficiency of the binding or storage system, and are not a reflexion of the insufficiency of the enzyme systems. Schanberg and Giarman[4,5] have shown that endogenous brain serotonin distributes itself between the particulate matter of brain homogenates and the supernatants, and that this relationship is susceptible to alteration by drugs. It was, therefore, of interest to investigate the sub-cellular distribution of serotonin in the developing rat brain and to determine whether it will parallel other maturational changes.

Rats of the Wistar strain, bred in our colony under standard conditions of management and nutrition, were used in this investigation, and were selected at various ages after birth. Animals were decapitated rapidly, the brains minus cerebella removed, weighed and homogenized in unbuffered 0·3 M sucrose containing tranylcypramine (1 μmole). All procedures were carried out at 4° C. Sufficient brains were pooled to give a homogenate dilution of 20 per cent (w/v). Duplicate aliquots of the homogenates were centrifuged for 30 min in a No. 40 rotor of the model *L* Spinco ultracentrifuge. The high-speed residue and supernatant were extracted separately for their serotonin content by the method of Shore and Olin[6], as modified by Mead and Finger[7] and assayed in concentrated hydrochloric acid as described by Bogdanski *et al.*[8]. All results are averages of six or more individual determinations, and represent 10–30 animals, depending on the age group.

Table 1. Wet Weights and Serotonin Content of the Developing Rat Brain

Age (days)	Brain wet weight–cerebellum (g)	Percentage of adult brain wet weight–cerebellum	5-HT (γ/g)	Brain 5-HT γ/gm as per cent of adult levels	Percentage of total 5-HT in residue	Ratio brain wt. 5-HT content
1	0·26	17·1	0 26	39·3	72·4	1·0
2	0·26	17·2	0·27	41·6	72 0	1·05
4	0·43	28·6	0·31	47 3	73 5	1·4
10	0·68	45·5	0 30	46·4	77·8	2·3
12	0·85	56·3	0 36	55·3	77·5	2·4
22	1·03	68 6	0·37	56 9	73 2	2·8
31	1 13	75·3	0·50	76·9	73 4	2·3
33	1 32	88·0	0·51	78·9	72 0	2·5
Adult	1 5	—	0·65	—	74·5	2·3

The weight of brains and the amine content of rat brains at various stages of development (Table 1) were obtained without the cerebellum. It is apparent that the rat brain at one day of age contains 39 per cent of the adult amine content, but only 17 per cent of the adult weight. The values for 5-HT content in the developing brain are in agreement with those quoted by Karki *et al.*[3]. At 1 day post-natally, the ratio of brain weight to serotonin is unity, and increases to 2·3 by 10 days. Thereafter, this ratio is approximately constant, suggesting that both wet weight and serotonin-levels are maturing at equal rates.

A number of investigators[4,9] have consistently observed that the bulk of endogenous brain serotonin (75 per cent) is associated with the high-speed residue. Our results show that homogenates prepared from rat brains at all ages from 1 day post-natally yield essentially an adult subcellular distribution, in that in excess of 70 per cent is recovered in the particulate fraction. The concentration of a number of enzymes, such as succinic dehydrogenase[10], cholinesterase[11], and glutamic acid decarboxylase[12,13], is low in the immature rat brain and increases slowly to adult levels. Typical adult electrical activity can only be recorded from the rat cortex at 2 weeks of age[14], and it has been suggested that mature bioelectric activity depends on completion of synaptic connexions in the cortex[15,16].

The suggestion has been made by Karki[3] that the immature rat brain cannot bind serotonin as efficiently as it does at maturity, and a similar phenomenon has been observed by Glowinski *et al.*[17] for the binding of circulating norepinephrine by the developing heart. Though the immature brain may be deficient in its ability to store serotonin, such differences are not evident in the present results on the sub-cellular distribution. It can only be suggested that if specific cellular components are responsible for the binding of small quantities of endogenous amine, then these components do not exhibit maturational changes which are qualitative in nature. It is tempting to speculate that the *in vivo* binding of serotonin might correlate with the maturation of synaptic vesicles, and also possibly to the biosynthesis of gangliosides. Possibly the cellular components responsible for the binding of serotonin are present at birth in the rat brain and mature at the same rates as the wet weight, and the total amine storage capacity, thus resulting in an essentially constant sub-cellular distribution.

Oscillation in Enzyme Reactions

The widespread existence of periodic phenomena in living organisms is well known. These events, like all other material phenomena in living systems, should ultimately be considered in terms of the individual chemical reactions occurring during the life process. Since chemical reactions occurring in biological systems are catalysed by enzymes, it was the purpose of our investigation to examine the possibility of oscillatory behaviour in enzyme-catalysed reactions.

The mathematical treatment of the differential equations arising in chemical kinetic problems is often impeded by the fact that the exact analytic solution of the equations is difficult, if not impossible, to obtain. Nevertheless, Lotka[1] in 1910 proposed an autocatalytic system wherein periodicity is clearly possible, and in 1921 Bray[2] illustrated experimentally a chemical system wherein periodicity is actually observed.

Difficulties attending the mathematical treatment of the differential equations arising in enzyme kinetic problems have served as a severe impedance to the development of enzyme kinetic theory. However, Christiansen[3] and Ozawa[4] obtained analytical results indicating that oscillations could occur in certain types of enzyme-catalysed reactions, provided certain conditions are met. Since then, Anderson[5], Chance[6] and Shnoll[7] have

Table 1. MECHANISMS INVESTIGATED FOR POSSIBLE OSCILLATORY CHARACTER

Mechanism		I	II	III
	$X_0 + S \rightleftharpoons X_1 \rightleftharpoons X_2 \rightleftharpoons \ldots \rightleftharpoons X_n \rightleftharpoons X_0 + P$	$n = 1$	$n = 2$	$n = 3$

Mechanism X	$X_0 + S_1 \rightleftharpoons X_1$ $X_0 + S_2 \rightleftharpoons X_2$ $X_1 + S_2 \rightleftharpoons X_3$ $X_2 + S_1 \rightleftharpoons X_3 \rightleftharpoons X_4 \rightleftharpoons X_5 + P_1$ $X_4 \rightleftharpoons X_6 + P_2$ $X_5 \rightleftharpoons X_0 + P_2$ $X_6 \rightleftharpoons X_0 + P_1$			

each obtained experimental results wherein periodicity is experimentally observed in enzyme systems.

The present investigation involves the examination of the behaviour of analogue computer simulations of each of the ten commonly encountered enzyme mechanisms listed in Table 1. The simulations were carried out on a *TR*-48 (solid state) computer, and the resultant concentrations displayed on an oscilloscope with time as the other axis. Hopefully, observations made for a large number and range of initial conditions and individual rate constants enable one to ascertain whether or not oscillatory behaviour should be expected for any of the mechanisms. The details of the procedure used for drawing inferences from this type of investigation are discussed elsewhere[8,9]. Briefly, negative results from this type of procedure are, strictly speaking, useless, but positive results are quite meaningful.

No evidence of oscillatory behaviour was found for any substrate or product (S or P) for any of the mechanisms listed in Table 1. Furthermore, no evidence of oscillatory behaviour for any form of the enzyme (X_i) was found for mechanisms I–IV in Table 1. On the other hand, the two-substrate, two-product mechanisms wherein more than one enzyme intermediate occurs (mechanisms V–X, Table 1) can experience up to three identifiable occasions when the intermediates pass through maximum or minimum concentrations. A typical example of the oscillatory behaviour is illustrated in Fig. 1.

Many other simulations were obtained wherein oscillatory behaviour occurred. We now define:

$$T = (t_2 - t_1)/t_{\frac{1}{2}}$$

where t_1 is the instant the first maximum occurs, t_2 is the instant the second maximum occurs, and $t_{\frac{1}{2}}$ is the time required for the products to grow from their initial concentrations (zero) to half their equilibrium concentrations, the equilibrium concentrations being defined in the absence of the enzyme. The general range of values found for T for mechanisms V–X, Table 1, is between 0·1 and 0·5. This range, however, can be extended in either direction by proper choice of the individual rate constants.

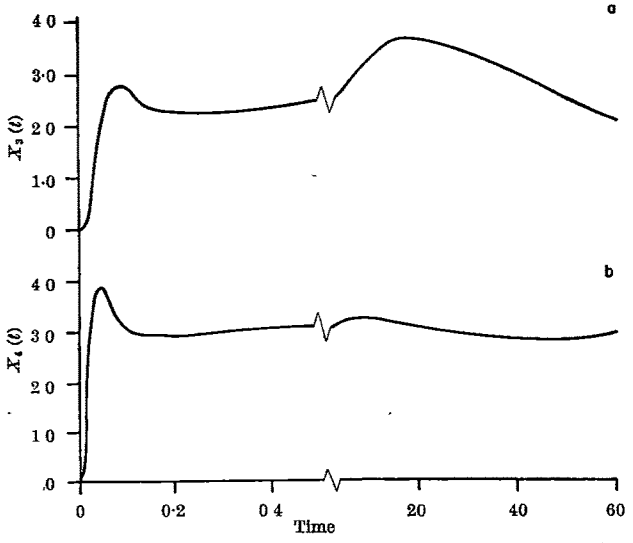

Fig. 1. *a*, A typical plot of $X_3(t)$ for mechanism X, Table 1. *b*, A typical plot of $X_4(t)$ for mechanism X, Table 1

I thank Dr. M. F. Morales for providing facilities in his laboratory for the 'experimental' part of this work to be done.

Highly Damped Oscillations in a Peroxidase-like Enzyme Reaction

RHYTHMIC biological processes are known to occur in most living organisms[1]. Even though these rhythms have been extensively investigated, little is known about their enzymatic or physical basis. Damped oscillations of glycolytic intermediates have been reported to occur in anaerobic yeast[2–5]. These findings heightened interest in oscillatory phenomena because the basis for these oscillations is more readily examined in this system. Indeed, simulation studies by Higgins[6] indicated that an activation of phosphofructokinase by fructose-1,6-diphosphate could produce oscillations similar to those experimentally observed. Another oscillatory system based on an inactive enzyme has been described by Spangler and Snell[7].

It is of fundamental importance to determine whether oscillations can only occur in enzyme systems having inhibition or activation of enzymes by other reactants, or whether most enzymatic reactions can oscillate. The present investigation indicated that any reaction involving two or more enzyme-substrate complexes has kinetic equations characteristic of damped oscillations, if the kinetic constants and substrate concentration satisfy certain conditions.

As a specific illustration, consider the peroxidase-like mechanism as follows:

$$\underset{(\varepsilon - p_1 - p_2)}{E} + \underset{x}{S} \xrightarrow{k_1} \underset{p_1}{E{\cdot}S_{\mathrm{I}}} \qquad (1)$$

$$\underset{p_1}{E{\cdot}S_1} + \underset{a}{AH} \xrightarrow{k_2} \underset{p_2}{E{\cdot}S_{\mathrm{II}}} + A \qquad (2)$$

$$\underset{p_2}{E{\cdot}S_{\mathrm{II}}} + \underset{a}{AH} \xrightarrow{k_3} E + A + \underset{p_3}{\text{product}} \qquad (3)$$

The pertinent kinetic equations are:

$$dp_1/dt = k_1x(\varepsilon - p_1 - p_2) - k_2ap_1 \quad (4)$$

$$dp_2/dt = k_2ap_1 - k_3ap_2 \quad (5)$$

$$dp_3/dt = k_3ap_2 \quad (6)$$

The solutions of these simultaneous non-linear differential equations do not exist in closed form. Fortunately, however, the general solution is not needed to demonstrate that damped oscillations can occur. Consider an open system in which the reaction vessel has sensors and a control unit to maintain the substrate concentration (x) and donor concentration (a) at constant levels after the reactants have been mixed. As a further simplification, assume that the two enzyme-substrate complexes and the product initially have zero concentration. Under these conditions, equations (4), (5), and (6) can be solved explicitly for p_1, p_2, and p_3 by using Laplace transforms[8]:

$$p_1 = \beta_1(1 - e^{-\gamma t}\cos\omega t) + \lambda_1 e^{-\gamma t}\sin\omega t \quad (7)$$

$$p_2 = \beta_2(1 - e^{-\gamma t}\cos\omega t) + \lambda_2 e^{-\gamma t}\sin\omega t \quad (8)$$

$$p_3 = k_3a\beta_2 t + \frac{k_3a}{\gamma^2 + \omega^2}\{(\omega\lambda_2 - \gamma\beta_2)(1 - e^{-\gamma t}\cos\omega t) - (\omega\beta_2 + \gamma\lambda_2)e^{-\gamma t}\sin\omega t\} \quad (9)$$

where

$$\beta_1 = \frac{k_1k_3\varepsilon ax}{\gamma^2 + \omega^2}, \text{ steady-state level of } p_1$$

$$\beta_2 = \frac{k_1k_2\varepsilon ax}{\gamma^2 + \omega^2}, \text{ steady-state level of } p_2$$

$$\omega = \sqrt{\Phi - \gamma^2},\ \Phi > \gamma^2$$

$$\gamma = 1/2\,(k_1x + (k_2 + k_3)\,a)$$

$$\Phi = k_3a\,(k_1x + k_2a) + k_1k_2ax$$

$$\lambda_1 = \frac{k_1\varepsilon x}{\omega}\left[1 - \frac{k_3\gamma a}{\gamma^2 + \omega^2}\right]$$

$$\lambda_2 = -\frac{k_1k_2\gamma\varepsilon ax}{\omega(\gamma^2 + \omega^2)}$$

t = time of reaction

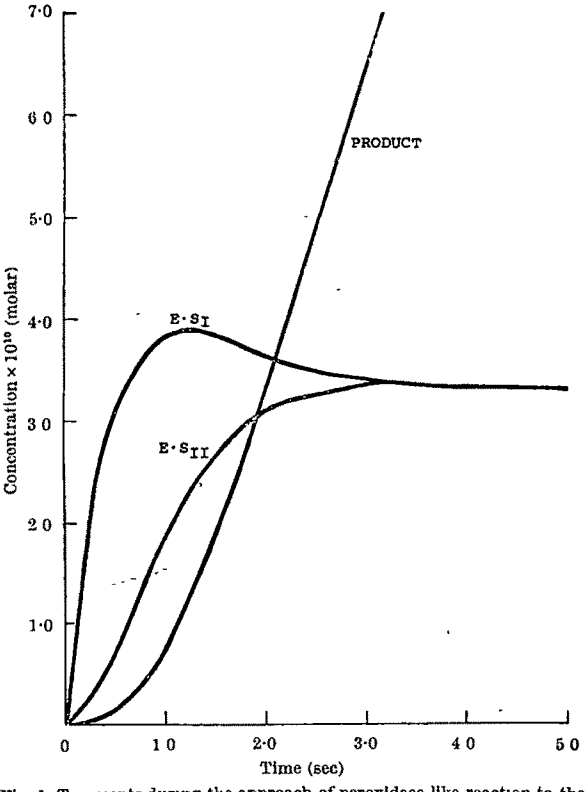

Fig. 1 Transients during the approach of peroxidase-like reaction to the steady state. $k_1x = k_2a = k_3a = 1{\cdot}0\ \text{sec}^{-1}$, $\gamma/\omega = \sqrt{3}$, $\varepsilon = 1{\cdot}0 \times 10^{-9}$ M

The sine- and cosine-exponential terms in equations (7), (8), and (9) indicate that the concentrations of the enzyme-intermediates will show damped oscillations. This condition will exist when Φ is greater than γ^2. The extent of damping is related to the ratio of γ to ω and is determined by the kinetic constants and substrate concentrations. Analysis showed that the oscillations will be least damped when the following conditions hold: $k_1x = k_2a = k_3a$. Even under these conditions, however, the oscillations damp out rapidly (Fig. 1). The oscillations are so small that an accuracy of one part in ten thousand is necessary to observe them. Thus, it is understandable that the analogue computer investigations[9] and also experimental measurements[10,11] of peroxidase kinetics have failed to reveal these damped oscillations, because the errors in these systems approach ± 10 per cent.

In summary, it appears that the oscillations in a peroxidase-like reaction are too highly damped to be observed experimentally with present techniques. Thus it appears that enzymatic reactions of systems such as peroxidase will have measurable oscillations only if some type of enzyme activation or inhibition is involved in a metabolic pathway.

This investigation was supported in part by contract *AT*(04-1) *GEN* 12 between the Atomic Energy Commission and the University of California and in part by U.S. Public Health Service grant *FR*-00007. Certain numerical calculations were made at the Computing Facility, University of California, Los Angeles.

Experimental Detoxification of Groundnut Meals containing Aflatoxin

During work involving sterilization by autoclaving of groundnut meals containing aflatoxin, the hepatotoxic metabolites of *Aspergillus flavus*, Link, ex-Fries[1], it was noted that an apparent reduction in the aflatoxin *B*1 content was induced when the normal methods of fluorescence assay[2] were afterwards applied to the sterile meal.

We have now demonstrated that sterilization by autoclaving at 15 lb./in.^{2} (120° C) of wet toxic groundnut meals resulted in a progressive reduction in their toxicity, due to aflatoxin *B*1, with time. Similar experiments involving treatment of pure aflatoxins (either produced by artificial culture or isolated from toxic extracts by preparative-scale thin-layer chromatography) resulted in the recovery of non-fluorescent products in which the characteristic ultra-violet absorption band at 363 mμ (ref. 3) had disappeared.

In a typical experiment, duplicate 20-g quantities of toxic groundnut meals (having moisture-levels of 10 per

(I) (II) (III)

cent and 60 per cent, respectively), shown by thin-layer chromatographic assay[2] to contain 7,000 μg/kg (7·0 p.p.m.) aflatoxin *B*1, were autoclaved at 15 lb./in.² (120° C) for 0·5, 2·0 and 4·0 h, respectively. After this treatment the samples were re-assayed, with the results shown in Table 1. The individual replicates in the two moisture-level series showed no significant differences.

Table 1. Effect of Autoclaving on Aflatoxin *B*1 Content of Toxic Groundnut Meals

Autoclaving time (h)	Moisture content (per cent)	Aflatoxin *B*1 content (μg/kg)
0 0	10	7,000
0 0	60	7,000
0·5	10	5,000
0 5	60	5,000
2·0	10	2,300
2 0	60	2,000
4 0	10	370
4 0	60	340

In order to ascertain whether autoclaving of toxic meals resulted in any significant alteration in their hepatotoxic effects, a sample (60 per cent moisture) containing 7,000 μg/kg aflatoxin *B*1 was autoclaved for 4 h and submitted, after re-drying, together with a similar quantity of untreated material, to the Central Veterinary Laboratory, Weybridge, for biological testing. Feeding trials were carried out using day-old Khaki-Campbell ducklings, both the original and the autoclaved meals being administered at two levels, representing 5 per cent and 10 per cent dietary incorporations, respectively, to matched groups of four ducklings. The category of toxicity of each prepared diet was assessed by histopathological examination of the liver tissue of both dead and surviving ducklings. Results are shown in Table 2.

Table 2. Effect of Feeding Autoclaved Toxic Groundnut Meal

Toxic groundnut meal	Level in diet (per cent)	Duckling deaths	Category of toxicity of diet
Untreated	5	1/4	High
(7,000 μg/kg *B*1)	10	4/4	Very high
Autoclaved	5	0/4	Very slight
(1,000 μg/kg *B*1)	10	0/4	Slight

From these results it was clear that autoclaving a moist toxic groundnut meal reduced its toxicity very considerably.

Autoclaving of pure aflatoxin *B*1 at 15 lb./in.² (120° C) for 4 h gave methanol-soluble, non-fluorescent reaction products in which no traces of starting material could be detected by thin-layer chromatography. Examination of the ultra-violet absorption spectrum of this solution showed that the characteristic peaks at 265 mμ and 363 mμ of pure aflatoxin *B*1 had disappeared to be replaced by a broad band at 258 mμ. Addition of alkali to this solution induced a bathochromic shift of 10 mμ to 268 mμ. Similar results were obtained using aflatoxin *G*1. The autoclaving treatment was applied also to a concentrate of aflatoxin *B*1 prepared from a toxic groundnut meal by separating and purifying the band formed on thin layers of Kieselgel '*G*' (Merck). (Three successive developments with 2 per cent methanol in chloroform and final desorption by methanol[4].) A similar result was again obtained.

Finally, 20 μg pure aflatoxin *B*1 was refluxed with water for 10 h. Extraction of the reaction products with chloroform, followed by thin-layer chromatography on Kieselgel '*G*' (Merck) as previously described[2], gave a blue fluorescent compound (R_F 0·32) not identical with aflatoxin *B*1 (R_F 0·50). The ultra-violet spectrum of this compound in methanol gave a well-defined band at 324 mμ, subsequent addition of alkali producing a bathochromic shift to 360 mμ. The spectrum of pure *o*-coumaric acid also showed a characteristic band at 324 mμ, alkali likewise inducing a bathochromic shift of 36 mμ. Aflatoxin *G*1 behaved somewhat similarly under these conditions.

In view of the known heat stability of the (anhydrous) aflatoxins it does not appear that the detoxification of meal by prolonged autoclaving can be explained by simple thermal degradation. As the presence of moisture is necessary it is likely that the first change is the hydrolytic opening of the lactone ring of aflatoxin *B*1 (I) to form a substituted *o*-coumaric acid (II). The aqueous hydrolysis experiment already described gives support to this, since one of the coumaric acid-type spectral bands was observed. However, after the autoclaving treatment this characteristic band was not seen, suggesting that more drastic changes ensued: for example, decarboxylation of the acid might occur (III), but in any event the way would then be open to further decomposition, leading to non-toxic breakdown products.

We thank Mr. A. B. Wood for ultra-violet absorption measurements, and Dr. Ruth Allcroft for the biological testing involved.

PHYSIOLOGY

Evidence for a Humoral Natriuretic Factor released by Blood Volume Expansion

Following the demonstration that diuresis and natriuresis, caused by blood volume expansion with iso-oncotic infusions in dogs, are similar in denervated and innervated kidneys[1], it was logical to attempt the direct demonstration by crossed perfusion of a humoral effector mechanism. This undertaking was preceded by the report of Mills *et al.*[2] that diuresis and natriuresis produced by iso-oncotic infusions in dogs could not be prevented by pitressin and mineralocorticoid administration. In the description by de Wardener *et al.*[3] of complicated cross-perfused whole-animal preparations, as well as of isolated kidney perfusions, evidence was advanced for the operation of a natriuretic material following large saline infusions in dogs. Cort and Lichardus[4], using carotid occlusion in the cat, have shown that a resulting natriuresis, presumed to be due to blood volume redistribution, could be elicited in a second cat by transferred blood. This experiment offered direct evidence of a natriuretic substance by a bioassay procedure in which the stimulus itself could not have influenced the test animal. A large amount of early work led Homer Smith[5] to deduce the existence of a natriuretic system other than the mineralocorticoid mechanism for regulation of sodium metabolism. Recently, evidence has been accumulating, in particular from the work of Levinsky, Rector and Berliner *et al.*[6–8], that expansion of the extracellular fluid volume with saline can decrease renal tubular sodium reabsorption in circumstances where neither change in mineralocorticoid levels nor in glomerular filtration rate can explain the effect.

In the crossed renal perfusions to be reported, carried out on pairs of hydrated anaesthetized dogs, we have observed transfer of a humoral effect increasing sodium

excretion and urine flow following modest infusions (30 per cent of estimated blood volume) of iso-oncotic solution or 'artificial blood'; the latter was previously shown by exchange transfusion to cause a renal response attributed almost entirely to the stimulus of intravascular expansion[9]. The results of the crossed renal perfusion have already been communicated briefly[10]. Animals were prepared for crossed perfusion from the femoral artery of the heparinized donor to an isolated aortic sac of the recipient connected to the left renal artery—the right renal artery being tied off. The renal venous return from an inferior vena cava sac was collected at constant pressure into a reservoir from which it was returned with a sigmamotor pump to the femoral vein of the donor. The connexion procedure involved no more than a few seconds of renal ischaemia. Arterial perfusion pressure was maintained constant (or deliberately altered) with a clamp on the perfusion line. Renal blood flow was measured directly by intermittent diversion of the venous return into a graduated cylinder, and filtration rate (GFR) and effective renal plasma flow (ERPF) were estimated by measuring exogenous creatinine and *para*-aminohippurate clearance, respectively. After control periods, the blood volume of the donor animal was expanded by infusion of 'artificial blood' consisting of washed canine erythrocytes resuspended in 6 per cent bovine albumin in Ringer–Locke solution. In other experiments the bovine albumin solution alone or the Ringer–Locke solution alone was used. Fig. 1 shows a

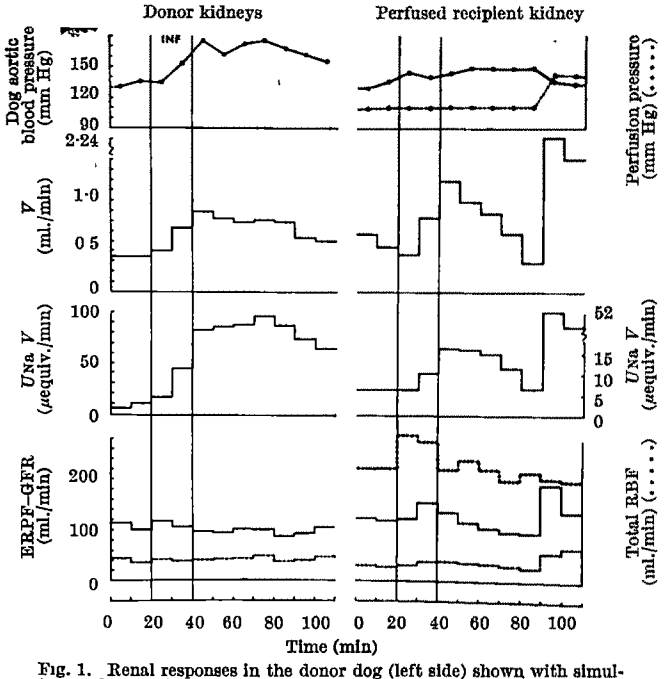

Fig. 1. Renal responses in the donor dog (left side) shown with simultaneously recorded responses in the perfused recipient dog kidney (right side) following infusion (INF) of artificial blood to the donor animal. The values for the perfused organ have been doubled. During the last two experimental periods, the clamp was removed from the arterial perfusion line

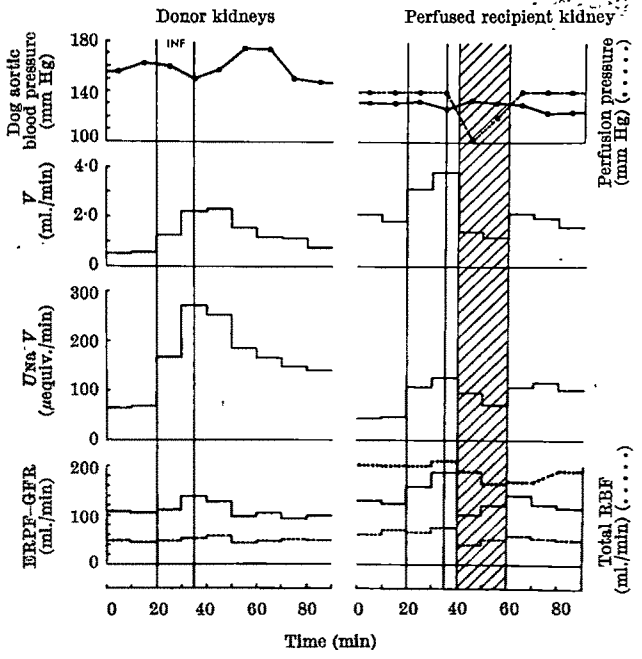

Fig. 2. Renal responses in donor dog and in perfused recipient dog kidney following infusion of Ringer–Locke's solution to donor animal. During the periods included in the hatched column the perfusion pressure was deliberately lowered; increased sodium excretion continues in spite of reduced GFR in the perfused organ

good response in the perfused kidney, with changes in some renal parameters representative of eight experiments with artificial blood as the infusate. Averaged data are given in Table 1.

The perfusion pressure was held constant at a somewhat reduced level (range of difference from donor blood pressure, 17–72 mm mercury, the average being 37) to enable regulation in spite of fluctuations and decline to normal of donor pressure after the infusion; that this contributed to the usually low output of the perfused organ is supported by the recorded effects of abrupt increase in perfusion pressure (Fig. 1). Although perfused at constant pressure, the recipient kidney consistently exhibited an increase in renal blood flow (RBF), attributable to vasodilation, during and immediately following the infusion to the donor. This change did not persist and was outlasted by increase in water and sodium excretion. The patterns of the latter in donor and perfused kidneys were not usually parallel; the peak natriuresis, on the average, was delayed in the recipient kidney as was the peak diuresis. Haemodynamic alterations, consisting of increasing values of GFR and ERPF in the perfused kidney, became stable or decreased in trend while the sodium and water excretion continued to increase. This observation, coupled with the demonstration (Fig. 2) in five experiments (using 'artificial blood' and other infusates) of persisting increase in sodium output above initial levels during deliberate reduction in GFR below control values (achieved by clamping the arterial perfusion

line), suggests that reduced tubular sodium reabsorption had also occurred.

It would appear that a humoral influence operated on these cross-perfused kidneys to produce natriuresis and diuresis related to the same changes in the donor animals. In view of the constant perfusion pressures, the associated increases in renal haemodynamic parameters were also of humoral origin. They may have contributed to, but are unlikely to account for, the alteration in output. The sub-normal output of the perfused kidney in the majority of our experiments may not be explicable entirely as an effect of reduced perfusion pressure and is the subject of further investigations. This shortcoming does not, however, in our view, invalidate the conclusion that a natriuretic substance (or inhibitor of an anti-natriuretic substance as discussed by Cort and Lichardus[4]) operated on renal excretion of sodium in response to the stimulus of blood volume expansion.

Effect of Glucagon on the Alkaline Phosphatase Activity in the Pancreatic Islets of Rats

ALKALINE phosphatases have been demonstrated by histochemical staining methods in the pancreatic islet cells of different species[1–4]. In the islets of adult mammals a positive reaction for this enzyme has so far been found only in the α cells[1,2], while in birds the reaction is present mainly in the β cells[3,4]. Since at least in mammals the islet α cells represent the site of glucagon production[5], it is noteworthy that Verne and Petkov[6] reported a diminished staining intensity for alkaline phosphatases in these cells after administration of glucagon to rats. In the present investigation the effect of glucagon on the alkaline phosphatase activity of the islet tissue has been re-evaluated by the application of quantitative chemical micro-methods to isolated pancreatic islets of rats.

Male Sprague–Dawley rats, weighing about 95 g and allowed free access to food and water, were separated into two groups: (1) Ten rats received subcutaneous injections of glucagon (Eli Lilly and Co.) dissolved in glycine–sodium hydroxide–sodium chloride buffer (0·1 M, *p*H 9·6), each injection corresponding to 0·3 mg glucagon per kg body-weight. The injections were given at intervals of 8 h until a total amount of 3·0 mg glucagon per kg body-weight had been administered to each animal. (2) Ten control rats received corresponding injections of buffer solution only. Three hours after the final injection the animals were killed by a blow on the neck and the pancreas rapidly excised and immersed in 0·25 M sucrose solution maintained at + 2° C. About 25 islets from each animal were isolated by free-hand dissection[7] and homogenized in 100–200 μl. ice-cold bi-distilled water. Homogenates of exocrine pancreatic parenchyma and of the liver were also prepared. The alkaline phosphatase activity was assayed in triplicate samples (10 μl. each) of homogenate at *p*H 10·0 as described by Bessey *et al.*[8]. The protein concentration of the homogenates was measured in triplicate samples (10 μl. each) according to Lowry *et al.*[9], and the enzyme activity was expressed as moles of substrate split per kg dry weight of a standard serum albumin reference (Armour Pharmaceutical Co., Lot 0370) and hour. It was ascertained that the substrate cleavage constituted a linear function of the incubation time and the enzyme concentration. For histochemical staining purposes small pieces of fresh pancreas were frozen at −70° C, and cryostat sections, 10μ thick, attached to glass microscope slides. The fresh sections were treated according to Gomori[10] using sodium-β-glycerophosphate (0·02 M) as substrate at *p*H 9·4. Incubations were carried out for 1–2 h at +37° C, control experiments being performed by incubating sections in a medium lacking the substrate.

There was a marked retardation of growth in the glucagon-treated animals, the body-weights of which had decreased no less than 18 ± 2 g at the end of the experiment. By contrast, the weights of the controls increased 16 ± 1 g. As can be seen in Table 1, the alkaline phosphatase activity of the islet tissue in the control animals was more pronounced than that of the exocrine parenchyma ($P < 0·01$), while it appeared less intense than in the liver ($P > 0·05$). Administration of glucagon brought about a marked increase of the enzyme activity in all the three tissues, the differences between control and experimental animals being significant at the 3 per cent level for the islets and at the 1 per cent level for the acinar tissue and the liver. A positive histochemical staining reaction was noted in the islets of both control and glucagon-treated rats, the staining being distinctly localized to cells at the periphery of the islets and to capillary walls. There was no obvious difference in the staining intensity between the two groups of animals.

Table 1

Animals	Islets	Acini	Liver
Control rats (10)	0·56 ± 0·09	0·24 ± 0·03	0·81 ± 0·14
Glucagon rats (10)	0·94 ± 0·13	0·46 ± 0·06	1·54 ± 0·20

Alkaline phosphatase activity in the endocrine and exocrine pancreas and the liver of controls and glucagon-treated rats. The figures denote mean value and standard error of the mean expressed as moles of substrate split per kg dry weight of standard albumin reference and hour. The number of animals analysed is given within parentheses.

There is much evidence to indicate that administration of glucagon brings about a marked functional depression of the islet α cells. Degranulation and atrophy of these cells were demonstrated in guinea-pigs[11] and rabbits[12] after prolonged courses of glucagon injection, and in rats a few days' treatment with this hormone exerted a significant reduction of the mean nuclear size of the α cells[13]. More recently it has been shown that morphological signs of a depressed α cell function actually are confined to the silver negative α_2 cells, supporting the view that glucagon production is a special feature of this type of α cell[14,15]. In addition to the regressive morphological changes, histochemical signs of a decreased α cell function have been demonstrated after administration of glucagon. Disappearance of zinc from the rabbit α cells was reported by Logothetopoulos and Salter[12], and Petersson and Hellman[15] observed a reduced staining for tryptophan in the α_2 cells of guinea-pigs. As mentioned here, reduction of the histochemically demonstrable alkaline phosphatase activity after glucagon injections has been reported in rats[6].

The present histochemical results agree well with the concept that non-specific alkaline phosphatases are distinctly localized to the α cells of normal adult rats. The positive staining reaction in these cells is in line with our quantitative data indicating a significantly higher enzyme

activity in the endocrine than in the exocrine pancreas. The previous observation of a diminished staining for alkaline phosphatases in the islets of glucagon-treated rats[6] was not supported by the present investigation. On the contrary, the quantitative chemical microassay clearly revealed that glucagon administration induced a marked rise in the enzyme activity level when expressed per unit protein. It seems, however, difficult to relate these results specifically to a depressed hormone secretion from the islet α cells, since the alkaline phosphatase activity was elevated also in the exocrine parenchyma and in the liver.

PHARMACOLOGY

Effect of Chlorothiazide on Water Consumption in the Rat

Chlorothiazide has been in use for several years as a diuretic drug. Its diuretic effect is usually ascribed to inhibition of sodium reabsorption in tubular cells[1]. In recent years chlorothiazide has been reported to decrease urine volume in diabetes insipidus[2]. The antidiuretic effect is accompanied, however, by saluresis, that is, increased sodium excretion[3]. To explain the paradoxical action of chlorothiazide it has been suggested that the drug could also affect thirst, by decreasing plasma osmolarity through increased urinary sodium loss[4,5]. We have recently reported that chlorothiazide reduced water intake in bilaterally nephrectomized rats, thus demonstrating an extra-renal effect[6]. Osmotic receptors related to thirst regulation have been postulated to be located in the hypothalamus[7,8]. Stein and Seifter have recently reported chemical excitation of thirst by deposition of acetylcholine crystals through a cannula into a certain area in the hypothalamus[9]. Applying their technique, we have deposited chlorothiazide crystals in the same area of the hypothalamus of rats, weighing 350–400 g, using the co-ordinates of Stein and Seifter[8]. In control animals either calcium carbonate or talc was deposited in the same location. Food and water were given freely and daily consumption was recorded. Water intake was found decreased in rats with hypothalamic chlorothiazide deposit compared with the control animals (Fig. 1). No difference in food consumption was noted between the two groups and the difference in water intake persisted also after withdrawal of the food. That chlorothiazide was not absorbed to any appreciable extent into the circulation was suggested by the lower urinary volume in the chlorothiazide rats relative to the control animals (20–26 per cent less). Furthermore, the potassium/sodium ratio in the urine was the same in the chlorothiazide and the control groups.

The effect of hypothalamic chlorothiazide deposition on water consumption was accentuated when hypertonic sodium chloride solution was injected subcutaneously to increase thirst. Animals, prepared as described here, received on alternate days 5 ml./kg of 4·5 per cent sodium chloride solution subcutaneously. The mean daily water intake during three days with hypertonic saline injection was compared with that during three days without such treatment. Four experiments were performed and the results are shown in Table 1. The results are expressed as the ratio of water consumption by the hypothalamic chlorothiazide group to the consumption by the control rats in each experiment. In all four experiments the depression in water intake by intrahypothalamic chlorothiazide was larger when hypertonic saline was injected.

Table 1. Comparison of the Effect of Intrahypothalamic Chlorothiazide on Water Consumption with and without Subcutaneous Injection of Hypertonic Sodium Chloride

	Relative water consumption* (per cent)			
Experiment No †	1	2	3	4
Without sodium chloride‡	93	74	54	92
With sodium chloride§	57	50	34	79

* Expressed as $\frac{\text{Water consumption of chlorothiazide group}}{\text{Water consumption of control group}} \times 100$

† In each experiment chlorothiazide was deposited into the hypothalamus in four rats and calcium carbonate was deposited in the corresponding area in four other rats (control group).

‡ Without sodium chloride—relative water consumption when no sodium chloride was administered

§ With sodium chloride—relative water consumption when 4·5 per cent sodium chloride was injected subcutaneously

In a further attempt to detect possible extra-renal effects of chlorothiazide the following experiment was performed. Rats deprived of water for four days were given 4·5 per cent sodium chloride solution, 5 ml./kg subcutaneously. This pretreatment was intended to increase the osmotic drive for drinking to the extreme. Thirty minutes later the rats were divided into two groups, four rats in each. One group was injected subcutaneously with chlorothiazide, 200 mg/kg, dissolved in dilute sodium hydroxide; the other group was injected with an equivalent volume of the solvent alone. Water was then given freely to both groups of animals. Within the next 5–10 h water consumption was found to be smaller in the chloro-

thiazide-treated rats than in the control rats (Fig. 2). This effect was found in four out of six experiments; in two experiments no significant difference was observed. (A possible explanation could be variation in intensity of thirst due to differences in humidity and ambient room temperature from one experiment to another.) The depression of water consumption by chlorothiazide in severely dehydrated, thirsty rats contrasted with the lack of effect or increased water intake induced by the drug in control experiments with hydrated rats. Dicker and Eggleton have recently reported decreased urine volume induced by hydrochlorothiazide in water-loaded rats[10], which seems to conflict with the results presented here. Hydration in their experiments, however, consisted of intragastric administration of a water load immediately after application of the drug. The possibility of delayed water reabsorption from the intestines caused by the drug has not been explored.

The experiments reported in this communication are consistent with the hypothesis put forward by Robson and Lambie[4] and Skadhauge[5] that the antidiuretic action of chlorothiazide in diabetes insipidus is through an extra-renal mechanism. However, these authors have assumed that sodium loss, caused by the drug, resulted in haemodilution, thus relieving thirst. This explanation has been recently challenged by Kennedy *et al.* in a thorough investigation on rats with diabetes insipidus[11]. They have shown that haemodilution induced by chlorothiazide in normal and obese rats failed to decrease water intake. They have also correctly argued that if decreased water intake were the only mechanism of action of chlorothiazide, there is no explanation why water deprivation does not cure diabetes insipidus. It seems that a combination of renal and extra-renal effects of the drug may offer better comprehension of the paradoxical actions of chlorothiazide. The renal action results in increased sodium loss (leading also to haemodilution). In addition, the drug may decrease the urge to drink by some action on the hypothalamic 'thirst centres', presumably through some effect on sodium transport in the osmotic receptors (which may be not dissimilar from the effect on kidney tubular cells). This, in turn, would result in decreased water intake and decreased urine output. Thus, increased solute loss through a renal mechanism combined with decreased water intake by inhibiting a central thirst mechanism could produce the effect of chlorothiazide observed in diabetes insipidus. This would eliminate the necessity of assuming chlorothiazide to inhibit sodium reabsorption and, at the same time, to increase water reabsorption by the kidney, which is required if a pure renal action is accepted[12].

HAEMATOLOGY

Xg Blood Groups of American Indians

ONE hundred and ninety-five Indians, mostly Navajo, from the area surrounding Santa Fe, New Mexico, were tested for the Xg^a blood group antigen with the following results:

	Xg (a+)	Xg (a−)	Total
Males	70	18	88
Females	100	7	107

The data were tested for mutual concordance of the gene frequency between sexes by the method of Haldane[1]. This method gave a normal unit variance test statistic with the value of approximately unity, so that there is no evidence of discordance between the sexes in this relatively small material.

The gene frequency estimate derived from the data is $q(Xg) = 0{\cdot}2636$, $p(Xg^a) = 0{\cdot}7364$. The information about the gene frequency, from Haldane's formula, is 998·81 units, corresponding to a standard error of the estimate of 0·0316. A 95 per cent confidence interval surrounding this estimate is:

$$Pr\ (0{\cdot}2017 < q < 0{\cdot}3255) = 0{\cdot}95$$

This estimate is significantly different from that found by Gavin *et al.*[2] for Caucasians, and is the lowest frequency so far reported for this gene in any population.

Hypothetical Significance of Disturbances of Zinc and Protoporphyrin Metabolism in Leukaemic Cells

ELSEWHERE[1,2] I have demonstrated a significant decrease in the zinc content of bone marrow and blood granulocytes in patients with acute and chronic myelocytic leukaemias, plasmocytoma and Hodgkin's disease, and in various patients with malignant neoplasms. Vallee and Hoch[3] isolated a zinc-protein containing about 0·3 per cent zinc from normal granulocytes. This protein contains almost all the water-soluble zinc in the granulo-

cytes[3]. In their opinion, this protein is an enzyme of unknown specificity. It is conceivable that the amount of this zinc-protein in granulocytes is decreased in leukaemic states. The results of Gordon[4], Saillen[5], Vanotti[6] and Walters[7], on the disturbances in haem and protoporphyrin synthesis in leukaemic cells, are also of interest. Free protoporphyrin can be demonstrated in these cells, but it cannot be shown in normal granulocytes. This means that the synthesis of an unknown protein with a protoporphyrin prosthetic group is inhibited in leukaemic cells.

The decrease in the content of zinc and the increase of free protoporphyrin appear to be closely related disturbances in leukaemic cells; a finding which may be important in the pathogenesis of leukaemia.

Craddock[8] suggests that a feedback mechanism is involved in the maturation of granulocytes, and has advanced the hypothesis of the presence of a protein in mature granulocytes which regulates the maturation of these cells. The humoral regulation of cell maturation is also suggested by Szent-Györgyi[9,10], who notes the lack of a protein regulating maturation in cancer and leukaemic cells.

In view of the aforementioned disturbances in zinc and protoporphyrin metabolism in leukaemic granulocytes, it is possible that the protein which regulates the maturation of granulocytes contains a zinc-protoporphyrin prosthetic group. Zinc-protoporphyrin proteins are known in animals and micro-organisms, and bivalent zinc may react with a protoporphyrin in the same way as does iron in haemoglobin or peroxidases, magnesium in chlorophyll, or cobalt in cyanocobalamine.

The treatment of leukaemic granulocytes with zinc-protoporphyrin compounds would be an investigation of great interest, but such compounds seem to be difficult to obtain.

One method of solving this problem may be to use micro-organisms to synthesize such a compound. Many bacteria are able to synthesize the zinc-porphyrin group and this may be why staphylococcal infection sometimes causes a remission in acute leukaemia.

Histochemical Demonstration of Sodium–Potassium-activated Adenosinetriphosphatase in Normal and Leukaemic Granulocytes

Sodium–potassium-activated adenosinetriphosphatase (Na–K-ATPase) is an enzyme regulating the active cation transport through the cell wall[1]. This enzyme differs from other ATPases in its great sensitivity to cardiac glycosides, and is inhibited by ouabain (strophantine *G*) at a 10^{-5} M concentration[2]. Na–K-ATPase systems have been demonstrated in various animal and human tissues[1,3,4]. In 1964 Block and Bonting[5] found Na–K-ATPase activity in leucocyte suspensions isolated from human blood. The close relation of this enzyme to the active transport of sodium and potassium in granulocytes was demonstrated. Block and Bonting also observed a significant increase in ATPase activity in leucocyte suspensions taken from cases of acute and chronic myelocytic leukaemia and chronic lymphocytic leukaemia[5].

In 1964, McChurkin[6] published a histochemical method for demonstrating Na–K-ATPase activity in tissue slices and confirmed the activity of this enzyme in muscle, kidney, brain and liver.

In the present work, McChurkin's procedure[6] was modified for an investigation of bone marrow and blood slides. The technique used here differs from the original technique in the method of fixation and the period of incubation. The slides were fixed for 10 min in cold (4° C) formalin vapour and then incubated for 3 h in a solution containing ATP (calcium salt), magnesium, sodium and potassium ions and *tris*-buffer (*p*H 7·8) in the proportions given in the original technique. The control reactions for other ATPases and non-specific alkaline phosphatase were carried out, and the inhibition of Na–K-ATPase with ouabain (10^{-5} M) was also performed. The percentage of cells containing Na–K-ATPase was measured using the 'score' method (range 0–4), as in the investigations of alkaline phosphatase activity in blood cells[7].

Ten healthy adults, five cases of acute myeloblastic leukaemia, three cases of chronic granulocytic leukaemia and four of chronic lymphocytic leukaemia were investigated.

The results are summarized in Tables 1 and 2, where the average values of Na–K-ATPase and ATPase activity are given.

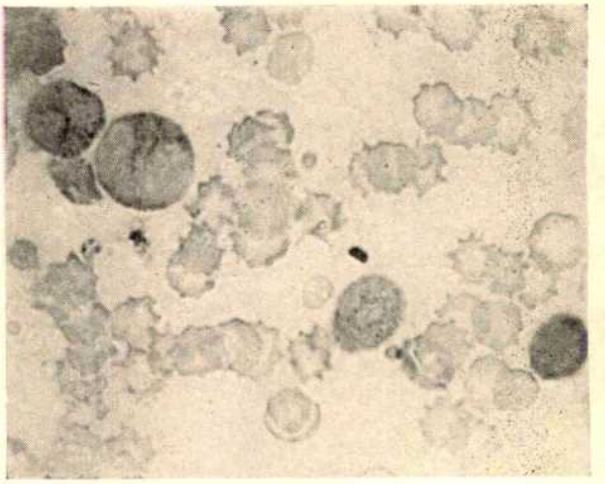

Fig. 1. Na–K-ATPase activity in normal granulocytes. Bone marrow. (×750)

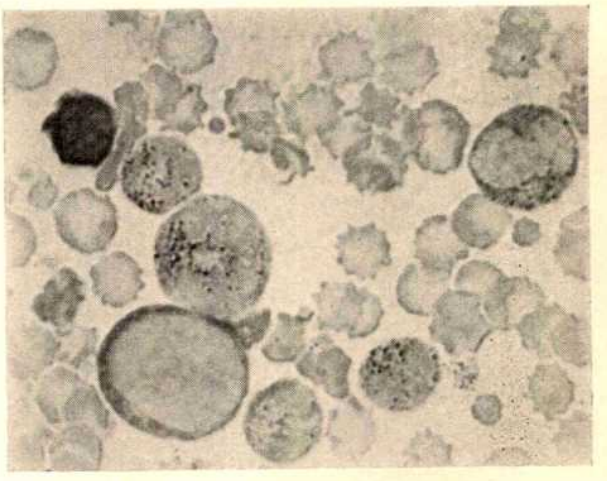

Fig. 2. Chronic myelocytic leukaemia. Bone marrow. Increased Na–K-ATPase activity in granulocytes. (×750)

Table 1. Na–K-ATPase and ATPase Activity in Bone Marrow and Blood Cells

	Normal cells	
	Na–K-ATPase	ATPase
Erythroblasts	–	–
Myeloblasts	±	–
Promyelocytes	+	–
Myelocytes	+	+
Metamyelocytes	+ +	+
Young granulocytes	+	+
Mature granulocytes	34·6% cells 42·1 score	12·8% cells 18·3 score
Lymphocytes	–	–
Reticulum cells	+	+
Blood cells:		
Granulocytes	26·4% cells 31·2 score	8·6 % cells 10·2 score
Lymphocytes	–	–

Table 2. Na–K-ATPase and ATPase Activity in Blood Granulocytes in Normal Adults and in Leukaemic Cases

	Na–K-ATPase	ATPase
Normal adults	26·4% cells, 31·2 score	8·6% cells, 10·2 score
Acute myeloblastic leukaemia	94·1% cells, 144·6 score	12·6% cells, 14·7 score
Chronic myelocytic leukaemia	63·6% cells, 98·7 score	14·1% cells, 18·2 score
Chronic lymphocytic leukaemia	38·2% cells, 49·3 score	10·6% cells, 12·6 score

Although these investigations were carried out on a small sample, the results show the differences between the activity of Na–K-ATPase and ATPase in granulocytes. The marked increase in Na–K-ATPase activity in leukaemic granulocytes (Fig. 2) is shown by comparison with the activity of this enzyme in normal granulocytes (Fig. 1). These results are similar to those obtained with the use of biochemical methods by Bonting and Block[5], but no Na–K-ATPase activity was demonstrated by histochemical methods in lymphocytes and no marked increase in activity was established in chronic lymphocytic leukaemia. The histochemical demonstration of Na–K-ATPase activity in blood cells seems to be a valuable complement to the biochemical technique, since it makes possible the cytological localization of enzyme activity.

The role of this increased activity of Na–K-ATPase in leukaemic cells in the pathogenesis of leukaemia is still not clear, but it indicates that the active transport of cations is disturbed in leukaemic cells.

PATHOLOGY

Experimentally produced Cerebral Status Spongiosus and Continuous Pseudorhythmic Electroencephalographic Discharges with a Membrane-ATPase Inhibitor in the Rat

In an experimental investigation of sub-acute spongiform encephalopathy[1], which, according to some authors[2,3], is a variety of Jakob-Creutzfeld disease, ouabain was intracranially injected into the rat.

The possibility was considered that the disease was due to some defect of membrane-enzymes, resulting in disturbances of water and electrolyte metabolism and possibly in status spongiosus. It is believed that in the cerebral grey matter there is an extremely limited extracellular space, and that glial cells are the pathway by which fluid, electrolytes and colloids are transported to and from neurones. Phosphatase activity has been implicated in the regulation of membrane permeability; ouabain is a powerful inhibitor of membrane-ATPase activity[4].

In rats injected intracranially with ouabain (0·3–0·6 mg in 0·25 m.c.c. of isotonic saline solution), a stereotyped response was observed. Shortly after recovery from ether anaesthesia, the rats showed striking motor activity; they ran swiftly through the laboratory, apparently unaware of obstacles, circling and jumping. Bursts of motor activity alternated with periods in which the rats lay quietly. This lasted for about half an hour and then generalized convulsions appeared; these became very frequent until one fit followed another with short intervals. After 2–3 h the convulsions became rarer; at this stage the rats lay in a coma but with their limbs almost continuously jerking. The survival time in this condition was variable; some rats died 3–4 h after the injection, others were still alive after 2–3 days and were killed with ether. For electroencephalographic recording two electrodes were implanted in the parietal bones before the intracranial injection; a third electrode was inserted in the nose to record rhinencephalic activity. The electroencephalogram was normal until the convulsions appeared; then there were multiple spikes in rapid rhythm alternating with high-voltage waves and, rarely, with wave-and-spike pattern. In the interval between the attacks slow waves of different type and pattern were recorded.

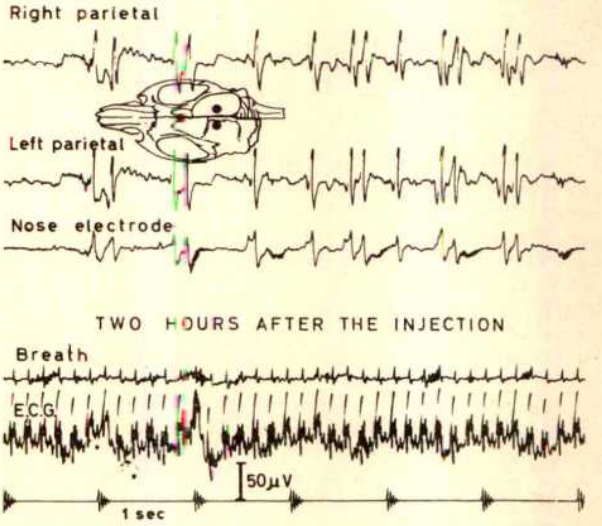

Fig. 1. Electroencephalogram 2 h after the injection. For interpretation see text

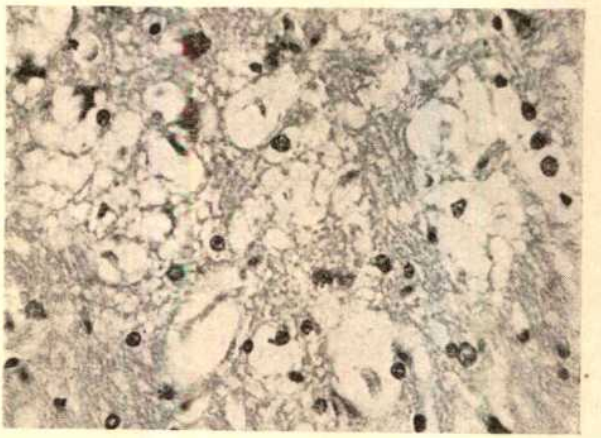

Fig. 2. Status spongiosus of the thalamus (65-h survival). (Haematoxylin and eosin, × *c.* 200)

When the convulsions had ceased and the rats lay motionless in a coma (the limbs were tied) the electroencephalogram showed a highly characteristic pattern constituted by long runs of regular, bilaterally synchronous high-voltage bi- or tri-phasic complexes at 50–70 per min. High-voltage slow waves were sometimes superimposed on this pattern.

Histological examination of the brain was carried out in two rats which survived for 55 h and 65 h after the injection. The most striking abnormality was severe cell loss and vacuolation of the 'ground substance' in the cerebral cortex and thalamus, amounting to true status spongiosus in some places.

We believe that this experiment lends support to the hypothesis that spongiform encephalopathy is due to some defect of membrane-enzymes. We should like to emphasize the similarity of the electroencephalogram findings, which are considered pathognomonic of the disease.

Enhancement of Transplantability of 3,4,9,10-Dibenzpyrene-induced Fibrosarcoma in Random-bred Mice

Three polycyclic hydrocarbons—3-methylcholanthrene (3-MCA) (refs. 1–3), dibenz (*a*, *h*) anthracene (DBA) (ref. 4) and dibenzo (*a*, *i*) pyrene (3,4,9,10-dibenzpyrene; DBP) (ref. 5)—have so far been shown to induce tumours antigenic to their isogeneic and/or their autologous host. The immunity produced is weak and can usually be overcome by a sufficiently large inoculum of tumour cells. Thus, tumours induced in inbred strains with these carcinogens take successfully on implantation into isogeneic mice, but give negative results in the allogeneic or random-bred strains[6–9]. Our investigations on the transplantability of the DBP-induced tumour into isogeneic and allogeneic mice agree with these findings. DBP-induced fibrosarcomata originally induced in strain *A*/Heston mice or *BALB*/*c* mice and transplanted into isogeneic hosts have been successfully transplanted, whereas the random-bred *CRCD*♀ mouse was resistant to allografts of the induced tumour and we concluded that growth failure was due to an allograft response.

To determine under what conditions allografts of DBP-induced fibrosarcoma would grow successfully in the random-bred mouse, Caesarean-derived *ICR*/*Ha* random-bred albino female weanlings (*CRCD*♀) obtained from the Charles River Mouse Farm, Wilmington, Massachusetts, were given a single subcutaneous injection of DBP (0·5 mg/mouse in 0·2 ml. tricaprylin) at the nape of the neck. When the induced subcutaneous tumours measured 1·0–2·0 cm in diameter they were excised aseptically; fragments were implanted by trochar subcutaneously into random-bred mice. The mice were housed in plastic or 'Fiberglas' cages, ten mice per cage, with a standard laboratory diet and tap water available *ad libitum*.

In our first series of experiments, 324 random-bred *CRCD*♀ females weighing 18–22 g were challenged subcutaneously with a 2 × 2 mm fragment of a primary DBP-induced fibrosarcoma. The pooled results (Fig. 1, Series I) revealed that the tumour graft had regressed in 310 mice and that 14 (4 per cent) of the mice showed progressive tumour growth lethal to the recipients. Forty-six mice in which the first transplant had regressed were later rechallenged with a second primary tumour fragment and only one mouse had a progressively growing tumour. The second grafts regressed more rapidly than the first grafts.

In a second series of experiments, when the DBP-induced fibrosarcoma had reached a diameter of 1·0–2·0 cm, thirty-two mice were auto-transplanted with their own surgically excised tumour. In each case a residuum of primary tumour was present. The results showed that the autograft had taken successfully in fifteen mice (43 per cent), demonstrating enhanced acceptance. To determine whether the host resistance could have been depressed by the presence of primary tumour, allografts of DBP-induced fibrosarcoma were transplanted into fifty random-bred mice bearing primary DBP-induced tumours, and thirty-six (72 per cent) of the allografts grew (Fig. 1, Series II). On the basis of these results, it is probable that acceptance of tumour autografts and allografts in random-bred mice bearing dibenzpyrene-induced sarcomata was due to a depression of the host response.

During the course of our experiments, Matsuyama and Nakamura[10] reported that a urethane-induced fibrosarcoma grew better in homologous mice bearing methylcholanthrene-induced tumours, whereas the tumours regressed completely in the normal homologous hosts, and concluded that the resistance was reduced in the mice bearing methylcholanthrene-induced sarcomata.

Previous investigations[3,11,12] have shown enhanced acceptance of chemically induced neoplasms in the second and subsequent transplant generations. In our third series of experiments, twenty-five mice were allografted with the primary tumour and twenty-five mice with a second generation transplant from mice bearing a primary and first transplant generation. Our results (Fig. 1, Series III) showed the typical allograft response to the primary tumour, whereas the second generation allograft grew in eighteen out of twenty-five mice (72 per cent) and was evidence that the antigenicity of the tumour had been lowered after the first transplant generation.

Thus, the random-bred mouse with its heterozygosity of genetic factors behaves similarly to homologous inbred strains with respect to selective pressures which enhance the acceptance of tumour allografts.

Differential Heat Sensitivity of Cells in Tissue Culture

IN the search for a specific fibroblast inhibitor that would not affect epithelial cells, a small but definite difference in heat sensitivity between these two cell types was noted.

Human fibroblasts were obtained from a skin biopsy and epithelial cells from carcinoma lines *C*-4 and *C*-27 [1]. Cells of either type were grown as pure cultures as well as mixed, in Leighton tubes with 11 × 55 mm windows. They were fed Waymouth's medium *MB* 752/1, supplemented with 10 per cent foetal calf serum.

The effects of conducted heat and of radiant heat were examined. Conducted heat was supplied by total immersion of culture tubes in water at temperatures ranging from 44° to 48° C. The source of radiant heat was four 3,200° K, 500-W studio flood lamps, separated from the cultures by a Corning infra-red filter No. *CS* 7-56. Inverted culture tubes were placed at a distance of 28 cm from the heat source. After heating by either method, cultures were cooled immediately, given fresh medium and observed for damage over several days. Experiments were performed on series of identical cultures, divided into groups of three tubes.

In one series of experiments, the proportion of surviving cells was determined by vital staining with neutral red and

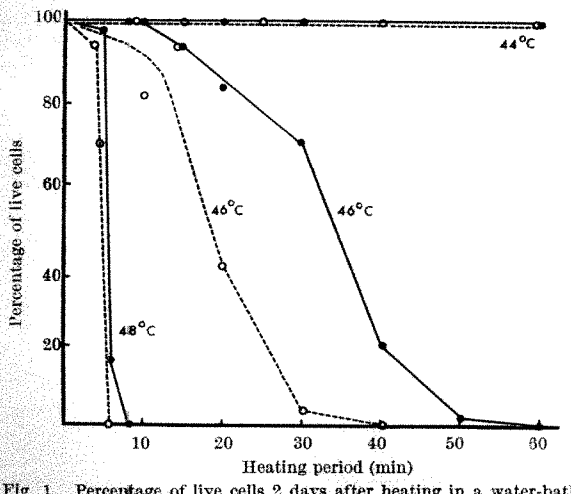

Fig. 1. Percentage of live cells 2 days after heating in a water-bath. ----, Fibroblasts; ——, epithelial cells

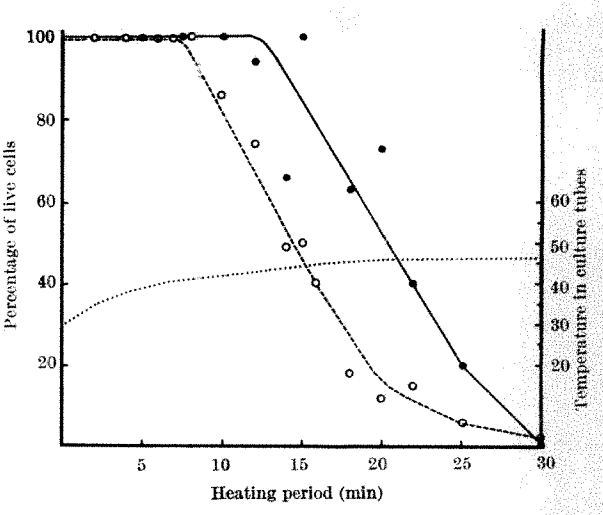

Fig. 2. Percentage of live cells 2 days after infra-red irradiation. ----, Fibroblasts; ——, epithelial cells. .....,, Temperature changes inside culture tubes, measured separately

counterstaining with trypan blue. There was little or no cell damage right after heating, but rather it reached its maximum after 2–3 days; then it often became obscured by new cell growth. Figs. 1 and 2 show the mean percentage of live cells 2 days after heating: fibroblasts were more sensitive to conducted heat as well as to infra-red rays. The figures are based on 109 and 180 observations respectively. While there was a definite differential effect of conducted heat at 46° C, both cell types responded similarly to 44° C and 48° C. In contrast to conducted heat, infra-red radiation killed 50 per cent of fibroblasts in 14 min, when the temperature in the culture tubes was only 44° C. 50 per cent of epithelial cells were killed by 20 min of irradiation, during which time the temperature had reached 46° C.

In an additional series of experiments, cultures were heated in a waterbath at 46° C for varying periods of time, and then cell protein per culture was determined at intervals on groups of tubes by the method of Oyama and Eagle[2]. As with results by vital staining, there was no difference between heated and control cultures on the day of heating; however, as shown in Table 1, 20 min at 46° C prevented any further increase in fibroblasts for the duration of the experiment, while epithelial cells resumed growth after a brief lag period. 46° C for 30 min prevented further growth in all cultures, and was followed by a gradual loss of protein due to the release of dead or injured cells from the glass. If the values in Fig. 1 are compared with Table 1, it becomes evident that many cells contributing to the protein value on day 2 were severely damaged or dead, and therefore further changes in protein content were probably the result of simultaneous dying and multiplication of cells with varying degrees of injury.

Figs. 3, 4 and 5 are examples of mixed cultures 2 days after exposure to infra-red irradiation for 0, 14 and 25 min respectively. The differential effect is illustrated in Fig. 4, with almost total loss of fibroblasts but no noticeable damage to epithelial cells.

These observations suggest that fibroblasts in culture are more heat-sensitive than epithelial cells, that cell

Table 1. EFFECT OF HEATING AT 46° C ON FIBROBLASTS AND EPITHELIAL CELLS IN CULTURE

Means of cell protein determinations on triplicate cultures, expressed as percentages of values on day 0.

death by this method is mainly delayed rather than immediate, and that radiant heat kills fibroblasts at lower environmental temperatures than does conducted heat. Exposure to 46° C for 20 min is being considered as a means to reduce fibroblast contamination in primary epithelial cultures.

IMMUNOLOGY

Immunological Tolerance as the Result of Terminal Differentiation of Immunologically Competent Cells

The nature of immunological tolerance, the unresponsiveness evoked by the administration of large doses of an antigen to newborns[1,2], is usually explained on the basis of the views of individual authors on the mechanism of antibody formation[3–6]. The solution of the problem has been transferred to the cellular level. Burnet[7], on the basis of the clonal selection theory, explained acquired tolerance as allergic damage and elimination of the predetermined cell after contact with the corresponding antigen. Other authors[8] assumed formation of the tolerant cell at various stages of its differentiation. Medawar[9] and Lengerová[10] suggested that the antigen might prevent normal maturation of reactive cells at the stage of the stem cell and that this induces the state of the immunological tolerance (heterogeneous model). On the other hand, some authors[11], on the basis of experimental data, assume that the onset of tolerance is possible at all stages of cell differentiation when antigen is present in excess (homogeneous model).

This communication presents experimental data supporting our former view[12] "that each specific immune inhibition develops on the basis of already existing or developing specific functions". This aspect was based on earlier experimental results[13]: new-born rabbits shortly after birth were injected with an excessive dose of antigen S. para *B* which is quickly deposited in tissues from blood circulation. The excessive dose accelerated and increased the antibody response in the new-born. After 4 months, these rabbits were injected with the same antigen and a significant inhibition of antibody formation was found in comparison with control animals or with animals injected shortly after birth with a smaller amount of the antigen. Thus the dynamics of the onset of immunological unresponsiveness found in new-borns was of the same character as the development of the immune inhibition in adults which followed the active immune response only[14–16]. It is usually impossible to find antibodies after the injection of large amounts of antigen to new-borns, especially when it persists in the circulation. Therefore all theories of immunological tolerance agree that the excessive amount of an antigen induces tolerance directly, without a previous immune response.

In the experiments presented here, antibody production was detected in individual cells by the plaque technique. The results indicate that a state of unresponsiveness follows antibody formation after large doses of an antigen.

New-born rabbits reared conventionally and colostrum-free piglets reared under sterile conditions were injected with increasing doses of sheep erythrocytes. The number of antibody-forming cells was detected by the plaque technique[17] in agarose[18,19]. Plaques were developed by addition of complement only (detecting 19 *S* antibody-forming cells) or by addition of anti-γG serum against rabbit or pig γG (detecting 7 *S* antibody-forming cells), diluted 1 : 50. The anti-γG serum was added either after the incubation of antibody-forming cells 1 h before the addition of complement, or mixed directly with the

agarose, erythrocytes and cells. This procedure increases the sensitivity of detection of 7 *S* haemolytic antibodies[20] and the number of antibody-forming cells during the secondary reaction[21].

After the primary injection of the antigen, the number of antibody-forming cells in the new-born increased simultaneously with the increased amount of antigen (Tables 1 and 2). Doses of antigen inducing tolerance immediately after the primary injection (that is, lowering the number of antibody-forming cells) have not been determined. The number of cells detected after the injection of the large dose of antigen into the new-born, an average of 100 antibody-forming cells per 10^8 lymphatic cells[22], may represent the total number of immunologically competent cells present in the organism, which are differentiated into producing cells, assuming that the large quantities of antigen inhibit the proliferation of the immunologically competent cells and their descendants.

Groups of experimental animals injected with various doses of sheep erythrocytes were revaccinated after 3 weeks with different doses of the same antigen (Tables 1 and 2). The number of cells producing antibodies after the secondary stimulus was significantly lower in the animals stimulated with maximum doses of the antigen during the primary reaction, that is in those animals that produced maximum of antibody-forming cells and highest titres of antibodies during the primary reaction. Inhibition does not result from accumulation of the persisting antigen with the new dose because the dose used for the secondary stimulation is below the level of the amount which stimulates antibody formation (Table 2). However, one large dose of antigen as the primary stimulus does not evoke complete tolerance. For the development of complete tolerance, especially for the inhibition of the formation of 7*S* type antibodies, repeated doses of antigen seem to be necessary.

On the basis of the results obtained we assume that acquired immunological tolerance may be considered as the result of the process of terminal exhaustive differentiation. In the excess of antigen almost all immunologically competent cells and their activated descendants are differentiated directly (without proliferation) into short-lived antibody-producing cells (about one per 10^6 cells). After their death, only a small number of cells capable of responding to specific antigen are available (state of tolerance). In contrast, small doses of antigen activate immunologically competent cells, but not all such activated cells are directly transformed to producing cells. Most of the activated cells proliferate, increase in number and form the basis for the secondary reaction when the second dose of antigen is injected. For establishment of tolerance in this situation (that is, for the exhaustion of all activated and proliferated cells), the quantity of an antigen administered must be related to the increased number of cells. This assumption may explain spontaneous escape of tolerance, induction of tolerance in adult individuals and even in individuals primed to give a secondary response. In this hypothesis, the inhibition of immune reaction (tolerance) as well as the preparation for secondary reaction is only the expression of various processes in the differentiation of immunologically competent cells.

Table 1. Antibody Formation in Young Rabbits immunized after Birth with Different Doses of Sheep Red Blood Cells (Srbc) and revaccinated 3 Weeks after the Primary Immunization

Dose of Srbc in primary immunization	Average number of plaque-forming cells per 10^8 lymphoid cells: 8 days after primary stimulus, Developed by complement	5 days after secondary stimulus with 2×10^8 Srbc, Complement only	Anti-γG + complement
0	0	2,585	732
1 ml. 0·01% Srbc (2×10^6 cells)	0	2,735	532
1 ml. 0·1% Srbc (2×10^7 cells)	3	14,070	102,433
1 ml. 1% Srbc (2×10^8 cells)	9	1,788	7,810

Immunization with Protein–Cellulose Co-polymer (Immunosorbent)

In order to prepare an immune serum with a high level of antibodies it is usually necessary to use many injections of soluble antigen. Antigens adsorbed on aluminium hydroxide or precipitated with alumina are frequently used for this purpose. Especially good results can be obtained using antigens mixed with different water–oil emulsions usually containing Bacille Calmette-Guérin (BCG)[1].

The very intensive production of antibodies which is obtained when such adjuvants are used is apparently conditioned both by the prolonged action of the antigen and by the non-specific effect of BCG, or by other components of the emulsion.

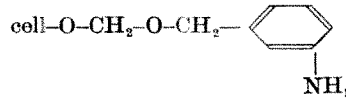
In our experiments we attempted to discover whether it was possible to induce the intensive biosynthesis of antibodies by introducing antigen into the body in another form, namely, in the form of a durable chemical co-polymer supported on an insoluble cellulose medium[2–6].

This method eliminated such factors of the normal adjuvants as the influence of organic or inorganic oil and microbial components. At the same time, however, the

effect of protracted presence of antigen in the body would still be manifested.

In the present work a protein–cellulose immunosorbent was prepared by coupling the protein antigen to the cellulose with the help of organic residues by the method described earlier. The co-polymer was prepared in the form of a suspension and was found to be convenient for the detection and isolation of antibodies[3–5]. It seemed advisable to use a similar suspension for the immunization, bearing in mind its extremely large surface and its comparatively high content of antigen.

Six Chinchilla-strain rabbits (males) were used in the immunization experiments. A γ-globulin fraction prepared from horse serum (HGG) by ethanol precipitation was used as antigen. Three were injected subcutaneously (on both sides) with a total of 25 ml. HGG–cellulose immunosorbent suspended in 0·9 per cent sodium chloride solution. These animals each received 212 mg sorbent (dry weight). This amount of immunosorbent contained nearly 25 mg of protein. At the same time, 100,000 units of penicillin and 200,000 units of streptomycin were injected into each rabbit. Three other rabbits were used as control. In all, they received 100 mg HGG in 10 ml. of 0·9 per cent sodium chloride solution injected as before.



Several months after the first immunization all the rabbits were injected again, this time with soluble antigen (HGG) only. The controls were injected after 4 months, and those treated with immunosorbent were injected after 5 months and 10 days. Injections were made from behind, at four points, into the muscles of the shoulder and the hip. Each received 150 mg HGG in 0·9 per cent sodium chloride solution with antibiotics (30,000 units of penicillin and 30,000 units of streptomycin). During the course of the experiment, after the first immunization and also after the second, samples of blood were periodically taken (about 15 ml. each time). The absolute amount of antibodies in serum was determined by measuring the absolute increase in protein on the immunosorbent[3,4]. All the animals used in the present experiment remained in good health during the course of immunization.

Results obtained are summarized in Table 1.

We also found the characteristics of the curves which show the changes in the quantity of antibodies in the serum after the second immunization. As shown in Fig. 1, in which the corresponding data are given, the characteristics of these curves are, on the whole, typical of those for curves normally obtained during ordinary re-vaccination, that is, there is a maximum and then a fall in antibody level.

At the same time, it follows from Table 1 and Fig. 1 that rabbits immunized with protein–cellulose co-polymer (immunosorbent) produced very large amounts of antibodies. This happened in spite of the fact that the quantity of antigen used for first immunization was four times less (25 mg) than in controls (100 mg).

An attempt was also made to find whether the rabbits first immunized with immunosorbent would produce not only the antibody against protein, but also the antibody against the insoluble basis of immunosorbent. To examine this question, rabbits Nos. 176, 182 and 195 were inoculated subcutaneously with the suspension of the following non-diazotized ether of cellulose:

with antibiotics (12,500 units of penicillin and 15,000 units of streptomycin). Each animal was injected with 125 mg of cellulose ether. This procedure was carried out 7 months after the administration of protein–cellulose immunosorbent. Tests for antibodies were performed 1, 2 and 3 weeks after the injection of the suspension of cellulose ether. The results are given in Table 1, which shows that antibodies specific to the insoluble portion of sorbent were not detected in the sera of experimental animals.

The data obtained demonstrate that the animals produced similar amounts of antibodies in response to the first administration of protein antigen which was firmly conjugated with insoluble cellulose, as they did in response to the administration of soluble antigen.

Over the 3 months of observation, immunosorbent produced a more protracted output of antibodies than did soluble antigen. Apparently some pronounced immunological reorganization occurs under these conditions. This is shown by the fact that animals first immunized with immunosorbent produce much more antibody in response to the new immunization than if they are first immunized with soluble antigen only.

The possibility of obtaining antisera with high levels of antibodies (up to 10–15 mg/ml.) recommends this method of immunization for the preparation of hyperimmune sera.

The data presented here show the significance of prolonged antigen action. They also show the necessity of

carrying out further experiments to find the most effective dose and periods for immunization with this product and to investigate the mechanism of its action. It is very likely that, in the future, it will be possible to prepare sera with still higher levels of antibodies by means of such immunosorbents.

BIOLOGY

Test-plants for Investigations of the Physiology of Fruiting in *Vitis vinifera* L.

Experimental work on the physiology of fruiting in woody plants is often made difficult by the large size of most mature fruit trees and vines. Many potentially useful techniques are denied the research worker, for example, growth of plants under closely controlled environmental conditions. The annual occurrence of the crop raises another difficulty because treatments must be applied and data recorded within the space of a few days or weeks, and the information obtained must suffice until the following year, as repetition of experiments in the same year is impossible.

A way of overcoming some of the difficulties inherent in research with woody plants would be to use small test-plants, that is, fruiting plants with essentially the same characteristics as field vines or fruit trees, but which are more amenable to experimentation. In this way, understanding of the factors controlling fruit set and development may be facilitated, and information from test-plants may ultimately provide the basis for less empirical field experiments.

In the orange and the grape vine (*Vitis vinifera* L.), progress has been made in producing fruiting test-plants. Using softwood cuttings, Gates, Bouma and Groenewegen[1] have propagated small orange trees which bear mature fruits within 15 months of striking the cutting. In the sultana vine (syn. Thompson's 'Seedless'), two methods of producing small fruiting plants have been developed. The first is by aerial layering of the present year's shoots[2], and the second by taking softwood cuttings from the present year's shoots after flower initiation in the primary buds[3]. These techniques overcome the problem of size of the experimental unit, but involve much labour and the maintenance of very large numbers of container-grown plants. In this laboratory, techniques have been developed which greatly simplify the production of small fruiting vines. Test-plants are raised in large numbers throughout the year, and used in physiological studies of fruiting. These plants are produced from single node one-year-old hardwood cuttings.

Hitherto, dormant one-year-old vine cuttings were unsuitable as a source of test-plants because inflorescence growth often ceases soon after bud burst. The rachis fails to elongate, and further differentiation of individual flowers is attenuated. Inflorescences remain attached to the plant for a few weeks, but later shrivel and drop off. Hence, in cuttings of most commercial varieties of *Vitis vinifera*, the potential of fertile buds to produce a bunch of grapes is rarely realized.

Experiments were carried out to detect the cause of failure of inflorescence growth in vine cuttings. Growth analysis showed little increase in the total dry weight of cuttings (that is, dry weight of old stem, new stem, leaves and roots) during the first month after bud burst. Initially, it appears that growth and respiration are supported to a large extent by reserves of the parent stem. Hence, leaves contribute little to growth, and may be considered as importers rather than as net suppliers of photosynthate. In cuttings, therefore, failure of the inflorescence to grow may be related to its inability to compete with leaves and other organs for available food supplies. This theory is supported by autoradiographic studies on field vines by Hale and Weaver[4], who showed that the inflorescence has limited ability to attract photosynthate until after the stage of fruit set. These observations suggest that surgical removal of competing organs might allow inflorescence growth to proceed unhindered.

Leaf removal proved the most successful treatment, for when leaves basal to the lowermost inflorescence, together with the leaf adjacent, were removed as soon as they appeared, growth and differentiation of that inflorescence took place. Plants were pruned to a single inflorescence for best results. After removal of the lower leaves, leaves produced distal to the inflorescence were allowed to grow out normally. Using the leaf dissection technique it was found possible to produce bunches, containing up to 100 grapes, from single node cuttings within 12 weeks from planting (Fig. 1).

Details of the technique are as follows. Dormant one-year-old vine shoots are stored under refrigeration (4° C) in sealed plastic containers. In collecting parent shoots care is taken to select for uniformity of diameter and internode length. Furthermore, shoots comprise six nodes, that is, buds number 4–10 inclusive from the point of insertion of the shoot on the vine. In this way, cuttings can be produced from buds of known position on the shoot should this be so desired. Shoots of the required variety are removed from cold-storage, and cut into single nodes. Each single node cutting is weighed and planted in a numbered 3 in. × 1 in. plastic propagating tube. At an arbitrary stage of bud burst, cuttings of similar original fresh weight, and at a similar stage of growth, are selected into groups. Dissection of leaves is carried out as soon as the first basal leaves appear beyond the brown bud scales, and continued as leaves appear until the required number have been removed. Within each group of treated plants further selection is made on the basis of inflorescence size (number of flowers), leaf number distal to the inflorescence, and shoot length.

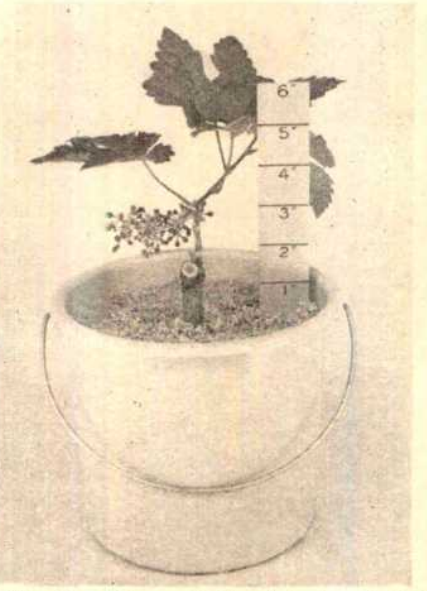

Fig. 1. Fruiting vine cutting var. 'Carbernet Sauvignon'. Photographed 12 weeks from bud burst. Leaves basal and adjacent to the inflorescence were removed as they appeared. Leaves distal to the inflorescence were allowed to grow out normally

After this final selection, plants destined for an experiment are transferred to 6-in. pots containing vermiculite, perlite or other suitable medium. Nutrients are provided by frequent application of half-strength standard Hoagland solution. In practice, more than 60 per cent of treated plants are discarded as a result of selection for uniformity. In this laboratory, 600 cuttings are propagated each month to provide continuity of supply of experimental material.

It might be argued that the test-plants described here are so unlike grape vines that their behaviour gives little indication of circumstances in the field. Experience so far does not support this criticism. Weaver *et al.*[5,6] have shown that the kinin '*SD* 8339', 6-(benzylamino)-9-(2-tetrahydropyranyl)-9H purine, has marked effects in increasing fruit set and size in field vines, including the 'Black Corinth' (syn. 'Xante Currant'). Using test-plants of this variety, parallel effects of '*SD* 8339' on fruiting have been observed. These results suggest that test-plants may be of particular value in the initial evaluation of effects of new growth substances on fruiting in vines.

I thank Dr. J. VanOverbeek for supplies of '*SD* 8339'.

Field Resistance in *Lolium* sp. to Leaf Rust (*Puccinia coronata*)

A high degree of 'field' resistance to infection by leaf rust (*Puccinia coronata* var. *lolii*) has been developed in perennial ryegrass (*Lolium perenne*), an open pollinated plant, by selecting individual plants for resistance (as one of several agronomic characters) from the progenies of open pollinated strains. The strains, selected by Corkill *et al.*, were tested for combining ability and other agronomic characters. Several were allowed to inter-pollinate to form the synthetic variety released as New Zealand perennial ryegrass[1].

A high degree of heterozygosity has been maintained in this variety. Although leaf rust occurs on a few individual plants it can rarely be transferred to neighbouring plants even though these may be infected; this indicates that physiological races of the pathogen are present. Neither the characteristics of the physiological races nor the genetic nature of the resistance against the pathogen are at present known. Resistance would appear to be due to an accumulation of genes within the variety but, because of the considerable and intentionally high degree of heterozygosity of individual plants, it seems probable that neighbouring plants are of different genotypes, and therefore owe their resistance to leaf rust to various combinations of a multiplicity of different genes.

This resistance to many physiological races of a pathogen, termed 'horizontal resistance' by van der Plank[2], though treated as a minor character by the plant breeders, was developed by breeding for 20 years a crop that previously had no noticeable resistance to the disease. A significant factor would appear to be that the breeding nursery was established in a locality which experiences severe natural infection of *P. coronata* var. *lolii* every summer.

Effect of Plant Regulators on the Incorporation of Phosphorus-32 into the Alcohol-soluble Fractions of Pea Seedlings

This communication reports experiments which we have carried out to examine and to compare some of the relations of the quantitative changes that ensue in the alcohol-soluble phosphorus fractions of pea seedlings, which have been induced by the effect of uncoupling and growth-regulating substances. In the course of the experiments, the changes in pea seedlings, which were treated with uncoupling and growth-regulating compounds *in vivo*, were recorded by labelling the phosphorylated products with ^{32}P-phosphate and paper chromatography.

If the uncoupling effect ensues, one may expect that the inorganic or the ester phosphate fractions accumulate and that the quantity of the nucleotides containing energy-rich phosphate decreases. Therefore, the changes in the following phosphorus fractions were analysed by measuring their phosphorus-32 activity: (1) inorganic phosphate; (2) ester phosphate; (3) phosphate coupled to an indole skeleton; (4) nucleotid phosphate. The ester fraction contains hexose and pentose phosphates, glyceric acid phosphate, adenosine monophosphate and a few unknown compounds with low phosphorus-32 activity. The indole phosphate fraction is an unknown compound which reacts in a similar manner to indole, sugar and phosphate, and if labelled with phosphorus-32 it becomes radioactive. The nucleotide phosphate fraction contains compounds which react in a similar manner to purine, sugar and phosphate, and their R_F-values are identical with those of the nucleotide polyphosphates.

Before the experiments were carried out, the plants were placed for 2 h in Knop's solution, diluted ten-fold and then (during the experiment) transferred into a solution containing ^{32}P-labelled potassium dihydrogen phosphate and the regulator. The controls were initially placed in a similar Knop's solution. The experimental plants were kept in the dark at 22° C for 24 h, and then the various phosphorus fractions were analysed by means of paper chromatography. Simultaneously, measurements were taken to determine the growth of the roots and shoots, and the c.p.m. and distribution of radioactivity established as a percentage of the total activity of the single phosphorus fractions.

The data in Table 1 reveal that the total activity is highest in the control plants, thus all three compounds applied decrease the amount of the soluble phosphorus compounds in the following order: DNP > SA > IAA. Similarly, all the substances examined decrease the incorporation of the phosphorus-32 into the nucleotide fraction. The proportion of the total impulses is as follows: the quantity of inorganic phosphorus-32 decreases in the sequence of C > IAA > SA > DNP; in the ester fraction the sequence is approximately the opposite—SA > DNP > IAA > C (C, control; SA, salicylic acid; DNP, 2,4-dinitrophenol; IAA, indolyl-3-acetic acid). The participation of the nucleotide fraction in the total activity is parallel to that of the inorganic fraction. It is present in the highest percentage in the control plant and decreases in the order IAA > SA > DNP. The activity of the fraction of indole-phosphate-32 is the highest from the point of view of both its total and percentile activity in the plants treated with IAA: the percentile ratio is IAA > C > SA > DNP; however, the difference between the c.p.m. and the percentile values is not significant.

Among the results, the most characteristic is the decrease which ensues in the phosphorus-32 activity of the nucleotide fraction in plants treated with regulators. This effect is greatest if typical uncoupling substances are applied, but it may also be observed in the case of IAA. The percentile increase of the ester fraction activity and the simultaneous decrease of the activity of the nucleotide phosphate fraction are striking.

Conflicting views appear in the literature concerning the uncoupling effect of the growth regulators from the point of view of their function in growth. Various authors have established that there is a close connexion between growth and phosphorus metabolism. Some authors interpret only the inhibitory effect; others[1–3], on the basis of the uncoupling of the oxidative phosphorylation, also the stimulating effect. According to the various opinions, the regulators exert their effect on the phosphorus metabolism directly[3–5], or indirectly[6,7]. Our experiments support the view that the IAA and the SA act directly on phosphorylation. This view is confirmed by the following: (1) the decrease of the nucleotide phosphate present and the simultaneous increase of the accumulation of the ester phosphate; (2) the similarity of the effect of DNP, SA and IAA; (3) the fact that it was possible to identify phosphorylated glycosides of indole compounds and phenolic acids in different plant organs.

The correlation between the uncoupling and growth-regulating effect is, however, very complex, because growth promotion or inhibition may both be associated with the uncoupling effect. This means that the growth regulation activity influences numerous other physiological processes. Further difficulties arise through the interpretation of the specific character of the regulating substances on the basis of the uncoupling effect. Thus, it seems that we cannot consider the uncoupling of the oxidative phosphorylation as a fundamental and general reaction of growth regulation.

Availability of Biologically Fixed Atmospheric Nitrogen-15 to Higher Plants

THE direct utilization by higher plants of nitrogen fixed by blue-green algae could play a substantial part in the Earth's nitrogen cycle. That certain species of blue-green algae can fix nitrogen when grown in solution culture is well established[1]. The maintenance of soil nitrogen supplies in rice paddy has been attributed to the growth and fixation of nitrogen by blue-green algae. Recently it was postulated that the blue-green algae may be important in the nitrogen economy of grazing lands[2–4].

The blue-green algae are known actively to excrete nitrogenous materials in solution culture[5]. However, the fate of nitrogenous products fixed by the blue-green algae and/or their associated organisms *in situ* has not been completely delineated. In rice culture it was suggested that algal-N became available to the rice plant following decomposition of algal tissue[6].

Surface soil encrustations of blue-green algae and associated organisms are found on semi-arid grassland soils[1]. Grass seedlings may be found rooted in the algal crusts where moisture and fertility conditions may be more favourable than on non-encrusted soils. Several grass seeds (*Artemesia* sp.) unexpectedly germinated in crusts under experimentation to assess the magnitude of nitrogen fixation. The use of atmospheric nitrogen-15 provided a means of tracing the products of nitrogen fixation and the possible ecological contribution of nitrogen to higher plants.

Native algal crusts were removed intact from the surface of desert-grassland soils. Excessive adhering soil was removed from the underside and 1 cm diam. cores were cut from the crust. Composite samples consisting of 60 random cores were placed in a desiccator containing 74·8 per cent nitrogen; enriched with 0·53 per cent atm. ^{15}N; 4·9 per cent carbon dioxide, 20 per cent oxygen and 0·3 per cent argon. The samples were moistened with de-ionized water by means of a cotton wick, and incubated in a plant growth chamber with 12 h days of 35° C with light intensity of 2,000 ft.-candles and 12 h nights at 18° C.

After incubation the seedlings were cut 1 cm above the algal crust and successively rinsed with 1 N HCl and de-ionized water. Nitrogen was determined by the Kjeldahl method using 1 : 3 : 1 sample : acid : salt ratio and a salt composition of K_2SO_4 : $CuSO_4$: Se in a 100 : 10 : 1 ratio on a weight basis. Digestion was continued for 6 h after clearing as recommended by Bremner[7]. Ammonia was recovered by alkaline distillation and prepared for isotopic nitrogen analysis by the hypobromite method[8]. We thank Dr. Arthur Edwards, Agronomy Department, Iowa State University, for the determination of ^{29}N/^{28}N ratios on the Consolidated Electrodynamics model 21–620 mass spectrometer.

Grass seeds (*Artemesia* sp.) germinated and grew for some time on an algal crust sample incubated for 160 days. At harvest the grass tops contained 1·22 mg nitrogen which contained 0·3733 per cent ^{15}N while the host crust nitrogen was enriched with 0·3813 per cent ^{15}N. Both enrichments were significantly greater than either the control crust sample (0·3648 per cent ^{15}N) or a commercial ammonium sulphate standard (0·3663 per cent ^{15}N).

The algal crust materials were lyophilized and ground with mortar and pestle to pass an 80-mesh sieve. Approximately 3·4 per cent of the total algal crust nitrogen was found to be water soluble, which included 1 per cent as water soluble ammonium-nitrogen. Both forms of soluble nitrogen contained significant isotopic enrichments of ^{15}N and may have been the form of labelled nitrogen taken up by the higher plant.

Thus, it appears that nitrogen taken up by the grass originated as atmospheric nitrogen, which was fixed by organisms in the algal crust and subsequently released in a form suitable for utilization by higher plants. Whether release of fixed nitrogen occurred via active excretion of nitrogenous products or followed decomposition of the biological nitrogen fixing organisms or both was not resolved. However, active nitrogen fixation was occurring in the algal crust at the 160 day harvest at the same rate as found on previous harvest dates (3, 6, 12, 24 and 52 days). The accumulation of fixed nitrogen was found[9] to fit a linear regression line with a correlation of $R = 0{\cdot}98$.

Soil nitrogen in grassland areas is depleted by removal by grazing animals and may be lost by soil erosion and denitrification processes. These losses gradually lead

to an impoverishment of soil nitrogen except where it may be replenished by biological fixation of atmospheric nitrogen or by artificial means. The evidence provided here indicated that the algal crust organisms fix atmospheric nitrogen and release it in forms available for uptake by higher plants growing in association with the crusts. The crust organisms appear to be an important source of nitrogen on semi-arid grassland.

Suppression of Schistosomiasis in Snails by Chloramphenicol

Chloramphenicol is known to inhibit protein synthesis in bacteria and in proliferating mammalian cells[1,2]. The experiments described here were undertaken to determine the effect of chloramphenicol on the protein synthesis which must occur during certain stages of the schistosome cycle when there is rapid growth or proliferation of the parasite. Following the penetration of a snail by a miracidium of *S. mansoni*, marked proliferation of the parasite occurs, leading to the development of tens of thousands of cercariae[3]. Snails exposed to miracidia were maintained in water containing chloramphenicol in an effort to inhibit protein synthesis and thereby to suppress formation of cercariae.

Fifty-two laboratory-reared snails approximately 12 mm in diameter, descended from a Puerto Rican strain of *Australorbis glabratus*, were used in these experiments. The snails were exposed overnight in 3 ml. of dechlorinated water to 15–20 miracidia of a Puerto Rican strain of *Schistosoma mansoni*. The miracidia came from eggs obtained from the livers of mice infected for 7–8 weeks.

On the day following exposure, the snails were divided into one group of twenty-six snails and two groups of thirteen snails each. Each group was put into 4 l. of dechlorinated water in covered stainless steel pans. The room temperature was maintained at 23° C; the water was aerated and the snails were fed lettuce *ad libitum*. The larger group (twenty-six snails) was untreated and served as the control group. Thirteen snails were kept in water containing chloramphenicol in a concentration of 625 parts per million (p.p.m.); the other thirteen snails were kept in water containing chloramphenicol in a concentration of 312 p.p.m. The water was changed each week and fresh chloramphenicol was added to water containing the two experimental groups. The treatment groups did not receive the drug between the third and fourth weeks as the water alone was causing some signs of toxicity in the snails. Five weeks after exposure to the miracidia and four weeks after exposure to drug, the snails were all placed in fresh water.

At six weeks the snails in each of the three groups were each placed in a medicine glass containing 3 ml. of water to see if they were shedding cercariae. At this point two of the control snails were dead but six of the surviving twenty-four snails were shedding. There were no deaths among the treated snails and none was shedding cercariae.

The shedding of cercariae by the control and experimental groups is summarized in Fig. 1. At 7 weeks, twenty-two of the twenty-four control snails were shedding cercariae, but at 7, 8 and 9 weeks none of the snails exposed to chloramphenicol was putting out cercariae. At 10 weeks, twenty of twenty-two control snails were shedding cercariae, two more having died. There was still no shedding of cercariae in either of the treated groups at 10 and 11 weeks and one death occurred in the snails that had been maintained at 625 p.p.m. At 12 weeks, however, four of the twelve remaining snails previously maintained at 625 p.p.m. started shedding cercariae, as did eight of the thirteen snails kept at 312 p.p.m. At 13 and 14 weeks the number of snails shedding from the greater concentration of chloramphenicol rose to 8/10 and to 8/8 as two more snails died, and those in the lesser concentration rose to 10/13 and 12/13. At 14 weeks the ten remaining control snails were shedding.

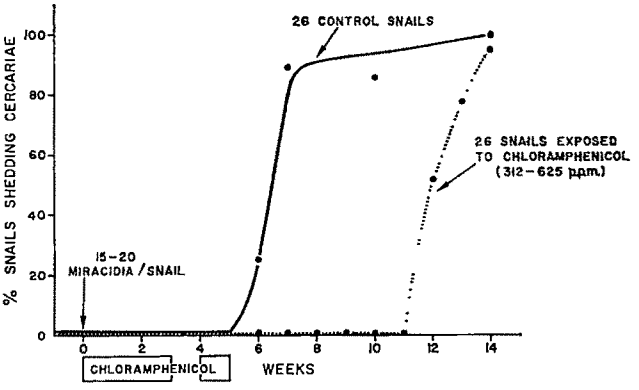

Fig. 1 The effect of chloramphenicol on the shedding of cercariae after exposure of *A. glabratus* to miracidia of *S. mansoni*

One major method of controlling schistosomiasis has been through the use of molluscicides[4]. To our knowledge no one has attempted to break the cycle through the prophylaxis or treatment of the disease in snails. The possibility of inhibiting protein synthesis during the rapid proliferation of the parasite from the miracidium to cercariae provided the rationale for an attempt to treat the infection in snails. The results indicate that, under the conditions used, chloramphenicol can suppress the development of the disease in snails, and that this suppression can be obtained with low concentrations which are not toxic to the snails. No deaths occurred until there was prolonged exposure to more than 1,000 p.p.m. of chloramphenicol. We have confirmed our initial results with an experiment now in progress using 280 snails in groups of 40 each. The drug at a concentration of 40 p.p.m. was completely effective in delaying the appearance of cercariae. However, the delay in development of cercariae was proportional to the time during which the infected snails were exposed to chloramphenicol. Thus, snails exposed to chloramphenicol over a 5-week period exhibited a 5-week delay in the shedding of cercariae as compared with the control groups. Similarly, in our present experiments, snails exposed to chloramphenicol for a shorter period of time exhibited a proportionally shorter delay in shedding of cercariae as compared with control groups.

The smallest concentration of chloramphenicol which is effective in suppressing the development of cercariae in snails is at present being determined. The possibility that *S. mansoni* may be more susceptible to chloramphenicol during other phases of the life-cycle of the parasite is also being examined. Conceivably other inhibitors

of protein synthesis may be more effective than chloramphenicol in interrupting the life-cycle of *S. mansoni*.

Dependence of the Olive Fly, *Dacus oleae*, Larvae on Symbiosis with *Pseudomonas savastanoi* for the Utilization of Olive

THE extracellular bacterium *Pseudomonas savastanoi* (Smith) Stevens has been suspected as a mutualist of *Dacus oleae* Gmelin for more than fifty years. Petri[1] described in detail how the bacterium was preserved through the pupal and adult stages in an oesophageal diverticulum in the head of the olive fly, and also discovered how the bacteria were transmitted from generation to generation. During oviposition the egg is smeared with the bacteria which are housed in invaginations near the distal end of the ovipositor. The bacteria enter the egg through the micropyle and ultimately become established in caeca arising from the anterior end of the larval mid gut. The functions of this symbiote, however, were not determined.

Other Tephritidae contain extracellular bacteria in special structures[2,3], but the nature of the symbiotic relationships has not been elucidated. Hellmuth[3] cultured isolated bacteria from various tephritids and concluded from the metabolic products in the culture substrate of *P. savastanoi* and *P. mutabilis* Hellmuth that these species produce aldehyde-like substances from proteins and that they can grow on media containing urea and uric acid as nitrogen sources. *Agrobacterium luteum*, also found in *D. oleae* at times[1], could only convert uric acid and not urea to protein-like compounds.

With the recent development of artificial media for larvae and techniques for culturing of *D. oleae* in the laboratory without olives[4], the symbiotic relationships were modified through the inclusion of antibiotics in the adult diet and acidification of the larval medium.

Forty-five pairs of adult *D. oleae* reared from olives were divided into three groups (Table 1). They were exposed to a standard adult diet consisting of 8 g fructose, 2 g enzymatic protein hydrolysate of brewer's yeast, and 10 mg choline chloride, in 10 ml. distilled water. The tests were conducted at 25° ± 1° C, 60–80 per cent relative humidity and under normal diurnal light.

There were three diets: a standard, the standard plus 50 mg of streptomycin sulphate, and the standard plus 50 mg streptomycin sulphate and 50 mg of uricase. Uricase was added to the third test diet when the possible uric acid metabolism by *P. savastanoi* was precluded by streptomycin.

The fertility of the flies was determined in the following way: on three different dates after an initial feeding of 20 days, green olives were exposed to the different groups of flies for a day and then held for at least 15 days at 25° C to allow development and pupation of *D. oleae* larvae. After 15 days all olives were dissected and the eggs or larvae were counted.

Table 1. EFFECT OF STREPTOMYCIN IN THE ADULT FOOD OF *Dacus oleae* ON THE DEVELOPMENT OF PROGENY IN OLIVES

Adult diet*	Oviposition date	No. of each larval instar dead in olives L1	L2	L3	No. flies produced
Control	2/17	0	0	0	12
	3/2	1	0	0	28
	3/15	0	0	0	13
Streptomycin	2/17	14	0	0	0
	3/2	25	0	0	0
	3/15	16	0	0	0
Streptomycin + uricase	2/17	18	1	0	0
	3/2	30	0	0	0
	3/15	11	0	0	0

Table 2. INFLUENCE OF DIETS CONTAINING ENZYMATIC PROTEIN HYDROLYSATES ON THE DEVELOPMENT OF APOSYMBIOTIC *Dacus oleae* LARVAE

Larval diet*	Amount (g)	No. eggs	Days to pupation	Wt. puparia $\bar{x}$ range (mg)	Per cent recovery $\bar{x}$ range
Soy meal	3	320	—	—	None
Soy hydrolysate†	3	331	11	6·1 (5·7–7·0)	34 (20–45)
Casein†	4	286	15	5·6 (5·3–6·0)	2 (0–11)
Casein hydrolysate†	4	398	11	7·0 (6·5–8·0)	33 (22–50)

* Basal larval medium: 25 g dehydrated carrot powder, 15 g brewer's yeast, 2 g agar, 0·05 g choline chloride, 15 ml. olive oil, 5 ml. 'Tween 80', 0·3 g sodium benzoate, 0·05 g *n*-butyl parahydroxybenzoate, 125 ml. distilled water and *p*H adjusted to 4·1 with 7 ml. 2 N hydrochloric acid.
† Nutritional Biochemicals Corp., Cleveland, Ohio.

The data (Table 1) show that flies fed the standard adult diet produced a normal progeny, while those adults that fed on diets with streptomycin produced larvae which failed to attain the third instar. With this latter group all eggs hatched in the olives, but all save one larva had died in the first-instar stage after tunnelling considerable distances. Thus, it appears that the bacterial symbiotes are indeed necessary to *D. oleae* larvae for the utilization of the olive flesh.

In order to answer the question as to whether streptomycin actually inhibited the bacteria or directly hindered the growth of the *D. oleae* larvae, the following tests were conducted. Using the techniques described by Hagen *et al.*[4], eggs were obtained from flies exposed continually to streptomycin; these eggs were placed on various prepared media. The types of media tested and the data obtained are shown in Table 2.

From these data it can be seen that enzymatic protein hydrolysates of either soy protein or casein permitted faster larval development, production of larger puparia and greater larval survival than when the unhydrolysed proteins were used. This suggests that *P. savastanoi* hydrolyses the protein in the olive flesh. This method of protein hydrolysis is perhaps reflected by the nature of the feeding habits of *D. oleae* larvae. The solitary larva of the olive fly feeds on fresh, usually solid, and relatively uncontaminated tissue as it bores through its host instead of feeding in a decaying substrate such as that normally ingested and re-ingested by a group of larvae in a single fruit characteristic of most other species of *Dacus*.

Prepared larval media adjusted to *p*H 4·1 also evidently destroyed *P. savastanoi* in the larvae of *D. oleae* even though the symbiotes made their entry into the embryo during oviposition by flies not fed streptomycin. The larvae developed normally in the acid medium if it contained hydrolysed protein, and adults from such aposymbiotic larvae are normal except where the larval morphological sites of the usual symbiotes were invaded by acidophilus bacteria, which at times were numerous enough to block mechanically the ovipositor in adults about 30 days old[4]. The first-instar larvae that hatch from eggs deposited in olives by flies containing these acidophilus bacteria do not develop to the second-instar, but eggs obtained from these infected adults and placed on media containing hydrolysed protein develop to adult flies. This verifies the significance of *P. savastanoi* acting as a mutualist, and indicates the inability of acidophilus bacteria to play the part of the normal mutualistic bacteria.

Besides performing protein hydrolysis, *P. savastanoi* may also be involved in the synthesis of methionine and threonine. Olive flesh analysed by one- and two-dimensional paper chromatography did not reveal the presence of these two essential amino-acids[5]. However, Diptera in which amino-acid requirements have been determined invariably require these two amino-acids for completion of larval development[6]. Since cystine also was not detected

in olive flesh[5], the possible sparing action of cystine for methionine is not likely either. The fact that aposymbiotic larvae of *D. oleae* cannot complete their development in olive flesh, with the assumption that these larvae require methionine and threonine, suggests that these amino-acids are synthesized by *P. savastanoi*.

It is interesting that *P. savastanoi* occurs as a pathogen of olive trees causing olive knot, and survives without the presence of the olive fly. In California, olive knot is common, and there are no *D. oleae* established in the new world. Therefore, *D. oleae* is not obligatory for the existence of the bacterium, but the olive and the bacterium are apparently essential in the ecosystem of the olive fly to-day.

Some Apparent Effects of Bithionol ('Actamer') on *Fasciola hepatica*

For some years my research has been concerned with the invasive stages of *Fasciola hepatica* in mammalian hosts. Young flukes have been tracked through the intestinal wall, the abdominal cavity and the hepatic parenchyma, and adults have been studied in the bile duct. Much evidence has shown that the flukes can break down many soft tissues which they encounter and has indicated that the fluke is, at all stages, a tissue feeding animal and not a blood feeder, as is commonly supposed. When I infected mice experimentally, dead flukes were not seen, although my investigations of X-irradiated flukes[1] have shown that flukes weakened in this way may be killed by phagocytosis. Band-type neutrophil leucocytes (polymorphs) penetrate the cuticle, spread throughout the cuticular core, and raise the epicuticle in blister-like formations which break down, leaving a stripped cuticle in a dying fluke. However, the leucocytes do not penetrate the base of the cuticle (lamina vitrea) and the disintegration of dead flukes is by secondary phagocytosis, so that this process differs from that reported by Standen[2] for drug-treated schistosomes. Standen has suggested that phagocytosis and drug action are related processes in schistosomes, and the possibility that this is so seemed to be worthy of investigation in liver flukes. However, my aim in a recent investigation has been to study any histological effects on the organs of *F. hepatica* when the rat hosts are treated with a drug.

My choice of bithionol as a suitable drug to use was made because this liver fluke and the lung fluke, *Paragonimus westermani*, display similar feeding activities and burrowing powers, and also because bithionol has proved to be potent in the treatment of paragonimiasis. Yokogawa[3] supported this contention of mine (see Dawes and Hughes, ref. 4) by noting the resemblance between the contents of the intestinal caeca of *P. westermani* during feeding operations and those of *F. hepatica* as described by me[5]. Regarding the potency of bithionol, it is known that dilutions less than 10^{-6} will kill excysted forms of *Paragonimus*, and Yokogawa (*loc. cit.*) considers this to be the most effective drug ever used in paragonimiasis, adding (p. 152) that this disease in man "will gradually die out in areas where mass treatment with bithionol has been thoroughly carried out". The antiseptic properties of bithionol (trade mark 'Actamer') are utilized in certain detergents and cosmetics, and the characteristics of the drug are described by the Hilton-Davis Chemical Co., Cincinnati, Ohio, in an undated publication.

In my experiments, ten young rats (weight about 300 g) each received five metacercarial cysts of *F. hepatica* by stomach tube and the infections were allowed to continue normally for 18½–34½ weeks. Eggs recovered from the faeces of the rats provided miracidia which infected laboratory-reared *Lymnaea truncatula*, proving that all infections were successful. Each of seven rats (*A–G*) began to receive drug treatment on day 131 and autopsy was carried out one day after administration of the final dose. The drug is almost insoluble in water and it was administered in suspension after 10 min shaking, using a stomach tube, and 10 mg constituted a single dose. Dosage was daily, so far as possible, and the rats received 2, 3, 4, 6 or 10 doses. Rat *H* did not receive any drug, and this control infection ran for 240 days, then yielding one living fluke measuring 18 × 10 mm and at least two flukes in serial sections of the bile duct. Two rats (*I* and *J*) carried their infections for 34½ weeks; each of them received three double doses of drug (20 mg daily on days 243–245) and was killed for autopsy on day 246.

Great effort was expended in the preparation of serial sections of the enlarged bile ducts of all these rats, together with any flukes which they contained, and sometimes recovered flukes, which were otherwise stained as whole mounts. From rats *A–G*, ten flukes 11–20 mm in length and 6·5–9 mm in breadth were taken alive, but these and also sectioned flukes all showed structural abnormalities which mainly affected the testes and the process of egg production, sometimes the cuticle and, to some extent, the vitellaria. Abnormalities of the testes are difficult to pinpoint at this stage for such a ramified organ, but numerous residual cytoplasmic bodies containing periodic acid–Schiff-positive materials are conspicuous in the tubules, within which there are numerous abnormal, curled spermatids, but relatively few typical sperms. The spermatids may have been liberated prematurely from their cytophores with consequent failure to complete their development.

This apparently general effect on the testes seems to have been brought about as a result of damage to the cuticle of the flukes, which is never phagocytosed but is often vacuolated extensively and sometimes loosened from underlying tissues and even stripped from some parts of the body both dorsally and ventrally, while there is no apparent damage to the intestinal caeca. Derangement of the egg-producing mechanism is probably due to faulty liberation of shell-forming materials from vitelline cells in the absence of sperms or else the presence of abnormally small numbers of sperms. It is evident in flukes from rats *B*, *C* and *D*, which received only three doses of drug, although the uterus of each of these flukes contains numerous eggs. Flukes from rats *E*, *F* and *G*, which received 4, 6 and 10 doses of drug respectively, show progressively diminishing numbers of eggs *in utero* until, in those from rat *G*, only very few malformed eggs appear. The ovary is apparently unaffected by drug treatment and isolated ova are plentiful in the oviduct and the nearby parts of the uterus. However, vitelline cells are not aggregated around the ova in the characteristic manner and typical sperms are evidently in short supply. Isolated vitelline cells, or small groups of such cells, sometimes have abnormal shells around them, and these cells also appear to be present only in sub-normal numbers, along with droplets of liberated secretion.

Neither of the rats *I* and *J* had any flukes in the hypertrophied bile ducts, which were filled with coarse, darkly coloured materials which are presumed to be the remains of flukes. Rat *J* was given a second infection of twenty cysts on day 211 and at autopsy (day 246) one living fluke of this infection was recovered entire from the liver, while sections of the liver revealed flukes in a dead or dying condition. There is thus some evidence, albeit scanty, that bithionol interferes with the reproductive function of *F. hepatica* and may kill flukes which are mature in the bile ducts or are maturing in the liver.

My collection of stained mounts of *F. hepatica* from various mammals includes two remarkable adults which are devoid of eggs. These specimens from the rabbit are notable because they also show derangement of the egg-forming mechanism. The oviduct is blocked with fragments of shell-forming secretion, the vitelloducts are closely packed with vitelline cells unable to continue their journey to the site of egg formation, and the vitellaria are completely degenerate. Sexual sterility has resulted in this instance from a simple physical effect on what might be called the assembly line of egg-production. The normal process by which the egg of a trematode receives its shell is subtle, and not fully understood. From the oviduct, vitelloducts and receptaculum seminis, respectively, an ovum, a cluster of vitelline cells and a rivulet of spermatozoa pass by a synchronized process into a special part of the oviduct (the ootype) and they become organized as a characteristic group, after which the shell appears by almost instantaneous liberation of secretion from the vitelline cells. From the time of witnessing the apparent disruption of this precision mechanism in the sterile flukes my opinion has strengthened to a belief that in seeking a drug that will eradicate flatworms it would be appropriate to try to interfere with this basic activity of producing shelled eggs rather than to try to kill or paralyse these worms. It would appear that bithionol shows some promise of providing just such an effect.

Oligomycin Inhibition of Ion Transport in Plant Roots

INVESTIGATIONS of ion accumulation by isolated animal[1-4] and plant[5] mitochondria indicate that a high-energy intermediate of oxidative phosphorylation provides the necessary energy for the ion transport process in these organelles. The intermediate can be formed by either substrate oxidation or directly by ATP. The antibiotic, oligomycin, which had earlier been shown to block one of the terminal steps of the phosphorylation sequence[6,7], does not inhibit the substrate-driven ion transport system but does inhibit the ATP-driven system[1-5].

It is not known whether ion transport across other plant cell membranes, such as the plasmalemma or tonoplast, is similar to ion transport across mitochondrial membranes. However, it seems possible that a similar ATP-driven system with the formation of a high-energy intermediate or other phosphorylated substance could also be operative in these membranes. Such a system might also be sensitive to oligomycin. Indeed, in the case of several animal tissues, that is, liver slices[9], red blood cells[10,11], and kidney cortex slices[11], oligomycin has been shown to inhibit K^+ uptake. Whittam *et al.*[11] have also shown that the $Na^+ + K^+$-stimulated ATPase activity of membranes from renal cortex tissue is inhibited by oligomycin in a fashion similar to the inhibition caused by ouabain. They further showed that Na^+ stimulated the incorporation of phosphorus-32, from terminally labelled ATP, into an acid insoluble fraction and that K^+ stimulated its discharge. Similar results were obtained by Charnock and Post[12]. Oligomycin and ouabain inhibited the K^+ stimulated discharge of phosphorus-32 from the protein. Thus, in the case of various animal membrane systems, it appears that a phosphorylated protein serves as an intermediate in ion transport and that oligomycin directly inhibits the transport process by blocking the functioning of the phosphorylated intermediate.

Although attempts have been made to demonstrate a comparable salt-stimulated ATPase system in higher plant tissues, the efforts have met with only limited success[13]. Therefore, in view of the effects of oligomycin already mentioned here, it seemed reasonable that an investigation of the effect of oligomycin on ion transport by whole roots might shed light on the nature of the ion transport system across plant membranes.

Roots of *Avena sativa* (oats) were used in most experiments. The seeds were planted on paper towels saturated with 0·1 mM calcium chloride and grown in a dark germinator (30° C) for 5 days. Entire root systems were excised, washed several times in 0·1 mM calcium chloride and then transferred into the experimental solutions. For examining the ion uptake the experimental solution contained 1 mM potassium chloride and 1 mM calcium chloride. Rubidium-86 (approximately 10,000 c.p.m./ml.) was added as a tracer of potassium. Absorption periods were generally for 1 h at room temperature (24°–25° C). The stock oligomycin was suspended in 95 per cent ethanol and all treatments were adjusted to contain equivalent amounts of ethanol. Experiments were terminated by draining off the experimental solution, rapidly rinsing the roots three times with cold de-ionized water and then placing the roots in cold de-ionized water for 15 min. The water wash was followed with a 15-min wash in an ice-cold 1 mM potassium chloride + 1 mM calcium chloride solution to remove exchangeable K(^{86}Rb). Aeration was provided during both the experimental periods and the washes. The roots were then blotted, weighed and extracted three times (10 min each) with 0·5 N nitric acid in a boiling-water bath. Aliquots of the extracts were plated and counted in a gas flow counter. Results are presented as μmoles K^+ accumulated/g fresh weight on the basis of the accumulated isotope.

Respiration studies were performed with the conventional Warburg apparatus. The experimental solution for the root respiration studies was identical to the ion absorption experiments.

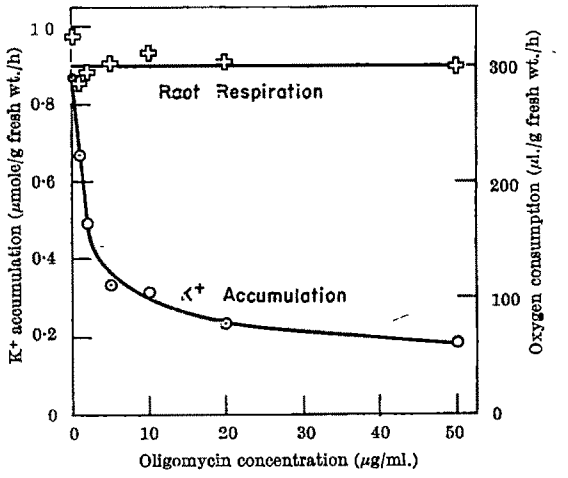

Fig. 1. Effect of oligomycin on K^+ accumulation and root respiration. See text for experimental procedure

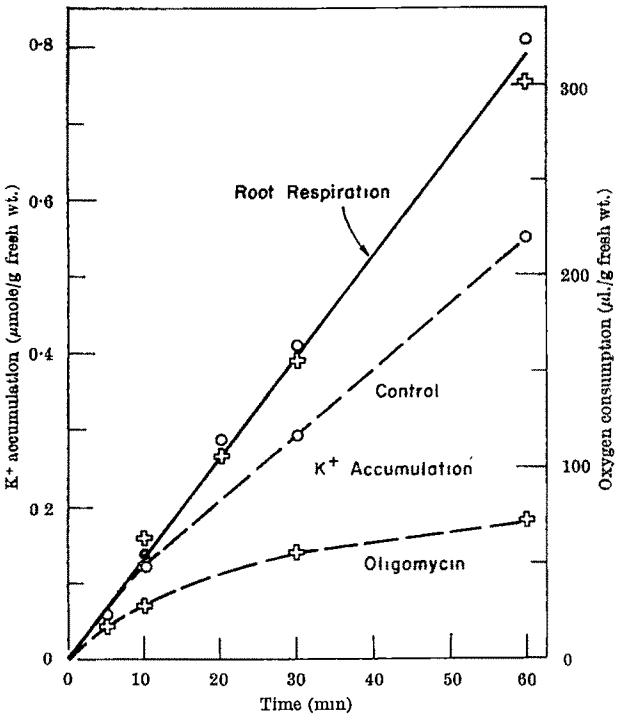

Fig. 2. Time course of K^+ accumulation and root respiration in the presence and absence of 20 μg/ml. oligomycin. – – –, K^+ accumulation; —, root respiration

The inhibitory effect of oligomycin on K^+ accumulation by excised oat roots is shown in Fig. 1. As little as 1 μg/ml. oligomycin caused a significant inhibition with half maximal inhibition occurring at a concentration of 2–3 μg/ml. These same concentrations of oligomycin had no significant effect on respiration of similar roots (Fig. 1). Fig. 2 shows that the inhibition of K^+ accumulation by 20 μg/ml. oligomycin is apparent within 5–10 min, while the root respiration is unaffected over a 1-h period. Additional experiments have shown that root respiration rates are unaffected by as much as 50 μg/ml. oligomycin over at least a 2-h period. It is well known that both oxygen uptake and phosphorylation by isolated mitochondria are inhibited by oligomycin[6–8]. This has been confirmed for mitochondria isolated from both the roots and shoots of oats. Thus, the lack of inhibition of whole-root respiration would imply that the antibiotic did not penetrate appreciably into the cell, and therefore, mitochondrial activity and the associated production of ATP should not have been limiting. This would suggest then that oligomycin was functioning to inhibit K^+ uptake by blocking ATP utilization in a process occurring primarily at the cell surface.

The inhibitory effect of oligomycin on K^+ accumulation was also found in other plant species although to varying degrees (Table 1). Roots which were most efficient in accumulation of K^+ showed the greatest inhibition to oligomycin.

Oligomycin inhibited accumulation of Cl^- and $PO_4^{\equiv}$ to about the same degree as K^+ (Table 2). However, accumulation of Ca^{++} was not significantly affected. There is some question, however, as to how much of the calcium uptake measured in experiments such as these actually represents active ion transport[14].

Table 1. Oligomycin Inhibition of K^+ Accumulation in Various Plants

Species	K^+ accumulated (μmoles/g fresh wt./h) – Oligomycin	+ Oligomycin	Inhibition (%)
Avena sativa (oats)	1·02	0·26	74·5
Lolium perenne (ryegrass)	0 38	0·14	63·2
Pisum sativum (peas)	0·30	0 17	43·4
Phaseolus vulgaris (bush bean)	0 17	0 16	5·8

The ryegrass was grown in the greenhouse for six weeks in sand culture receiving daily watering with complete nutrient solutions. The peas and beans were grown in the dark in vermiculite and distilled water for six days. Roots were washed free of adhering sand and vermiculite, excised and placed into the experimental solutions. Oligomycin concentration was 20 μg/ml

Table 2. Effect of Oligomycin on Ion Accumulation by Oat Roots

Ion	Accumulation (μmoles/gm fresh wt./h) – Oligomycin	+ Oligomycin	% inhibition
K^+	0·725	0 287	60 4
Ca^{++}	0·373	0·358	4·0
Cl^-	0·376	0·173	54·0
$PO_4^{\equiv}$	0·292	0·113	61·3

^{86}Rb, ^{45}Ca, ^{36}Cl and ^{32}P were used as the tracers for potassium, calcium, chloride and phosphate, respectively. Solutions contained approximately 10,000 c.p.m./ml. Oligomycin concentration was 20 μg/ml.

Inasmuch as oligomycin inhibits respiration of isolated mitochondria but does not affect the respiration of roots, it can be deduced that the antibiotic is not penetrating into the cells in any appreciable quantity. Furthermore, the inhibition of salt uptake is noticeable within 5–10 min. These observations are taken to mean that oligomycin is acting at the cell surface. The plasmalemma must contain an oligomycin-sensitive transport system, similar to that found in various animal membranes[9–11]. There is one distinction to be made: ouabain apparently acts like oligomycin on animal membranes[11], but I have been unable to detect any ouabain inhibition of accumulation of K^+ in plant roots. In addition, oxidative phosphorylation and the ATP-driven accumulation of calcium and inorganic phosphorus in isolated plant mitochondria[5] are unaffected by ouabain.

A search is now being made to determine whether the plasmalemma contains a salt-stimulated ATPase, and to determine its response to oligomycin.

Differences in the Lactic Dehydrogenases of Primate Brains

In mammals, lactic dehydrogenase (LDH) has five molecular forms which show species and tissue specific patterns by starch-gel electrophoresis[1]. These molecular forms appear to be tetramers of two different polypeptide sub-units in their five possible combinations[2,3]. The two types of sub-units have been termed '*A*' and '*B*' (ref. 2), or '*M*' and '*H*' referring to their predominance in skeletal muscle and heart respectively[3]. The *M*(uscle) type of lactic dehydrogenase is best suited for anaerobic metabolism and the *H*(eart) type is best suited for oxidative metabolism[3,4]. Since glycolysis or anaerobic metabolism is phylogenetically more ancient that aerobic metabolism[5], a shift in certain tissues from *M* LDH to *H* LDH would be expected during the phylogenetic development of higher animals. From a comparative study of lactic dehydrogenases in a small series of vertebrate brains, Bonavita and Guarneri[6] provided evidence that this trend occurred during the emergence of warm-blooded

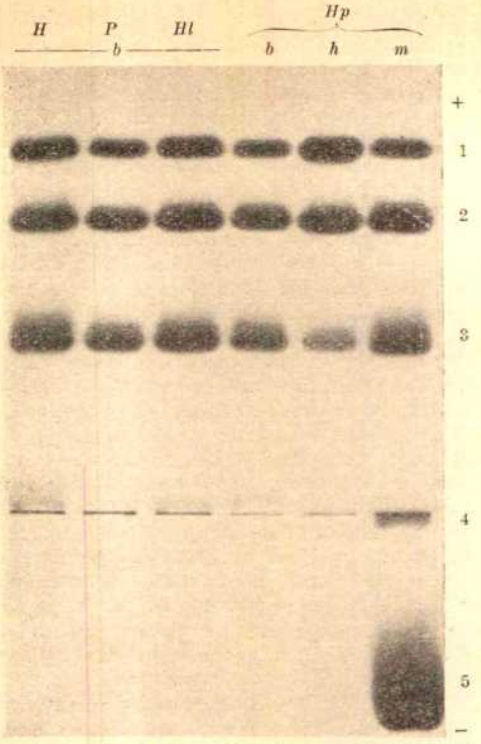

Fig. 1. LDH patterns of brains (*b*) from *Homo sapiens* (*H*), *Pan troglodytes* (*P*), and *Hylobates lar* (*Hl*), and of brain (*b*), heart (*h*), and skeletal muscle (*m*) of *Hylobates pileatus* (*Hp*)

vertebrates. The present communication provides evidence that such a shift was still occurring during the evolution of the order Primates.

The primate forms (Table 1) used in this study consisted of tree-shrews, lorisoids, tarsiers, ceboids, cercopithecoids, and hominoids, which show in the sequence mentioned an increasing phylogenetic relationship to man[7]. Brain, heart, and skeletal muscle, recovered as quickly as possible from these primate forms, were used immediately or stored for a few days at −18° C before being used. The tissues were homogenized in cold 0·05 M *tris* buffer *p*H 7·4, using three parts buffer to one part tissue. The supernatants obtained by centrifugation at 20,000*g* for 20 min were subjected to vertical starch-gel electrophoresis at 4° C for 16 h by the technique of Smithies[8], using the gel conditions described by Boyer *et al.*[9]. The gel was then bisected and the halves placed in a solution of 0·05 M sodium lactate, 0·0004 M NAD, 0·3 mg/ml. nitro blue tetrazolium, 20 μg/ml. phenazine methosulphate, and 0·05 M *tris* buffer, *p*H 7·4. After incubation for 1 h at 37° C the zones or bands of LDH activity developed in the gel. The pure *H* LDH gave the band of fastest anodic electrophoretic mobility (band 1); the pure *M* LDH gave the band of slowest mobility (band 5); and the hybrids of *H* and *M* gave the three intermediate bands. The formulae for these five bands are: (1) H_4; (2) H_3M_1; (3) H_2M_2; (4) H_1M_3; and (5) M_4.

Table 1. The Primate Forms and Number (in Parentheses) of Animals Examined in this Investigation

Hominoidea
- *Homo sapiens*, man (6).
- *Pan troglodytes*, chimpanzee (3)
- *Hylobates lar*, gibbon (2)
- *Hylobates pileatus**, gibbon (1)

Cercopithecoidea
- *Colobus polykomas*, colobus (3)
- *Macaca nemestrina*, pig-tail macaque (1)
- *Macaca mulatta*, rhesus monkey (1)
- *Macaca irus*, cynomolgus monkey (2)
- *Cercopithecus aethiops*, vervet (2)

Ceboidea
- *Ateles*†, spider monkey (1)
- *Alouatta*†, howler monkey (2)
- *Cebus*†, capuchin monkey (3)
- *Saimiri sciureus*, squirrel monkey (3)
- *Callicebus*†, titi monkey (2)
- *Aotes trivirgatus*, night monkey (2)
- *Oedipomidasoedipus*, cotton-top marmoset (2)

Tarsioidea
- *Tarsius syrichta*, Philippines tarsier (2)

Lorisoidea
- *Galago crassicaudatus*, greater bush-baby (5)
- *Galago senegalensis*, lesser bush-baby (1)
- *Nycticebus coucang*, slow loris (4)
- *Perodicticus potto* (1)

Tupaioidea
- *Tupaia glis*, tree-shrew (7)

The chimpanzee, gibbon, colobus, rhesus and squirrel monkey tissue were shipped to us in dry ice from the Delta Regional Primate Research Center of Tulane University. Tarsiers were sent from the Philippines and died in flight just before arriving in Detroit. Human brain was from autopsy made 6 h after death. All other animals were killed in the laboratory.

* The species name used for this specimen by the Delta Regional Primate Research Center is considered a synonym for *Hylobates lar* by Fiedler (ref. 7).

† The exact species classification of these specimens has not been determined.

Fig. 1 shows the LDH patterns in the brains of different members of the Hominoidea (man, chimpanzee, and the gibbons). In these patterns there are large amounts of bands 1, 2 and 3, and only trace amounts of bands 4 and 5. As can be noted in the figure, the brain patterns are much more similar to the heart pattern of gibbon than to its skeletal muscle pattern. No variations were observed among these hominoids in the mobilities of their LDH bands. This uniformity of brain LDH pattern extended to all the catarrhine primates listed in Table 1: the various members of the Cercopithecoidea (colobus, pig-tail macaque, rhesus, cynomolgus and vervet monkeys) as well as to the members of the Hominoidea.

Fig. 2 compares the brain LDH patterns of six ceboids (howler, capuchin, squirrel, night and titi monkey and cotton-top marmoset) to that of the vervet (a catarrhine monkey). The *H* LDH of these ceboids had the same mobility as *H* LDH of the catarrhines. However, the ceboid *M* sub-units had a faster anodic mobility than the catarrhine *M* sub-units since bands 2, 3 and 4 had more anodic positions in the ceboids than in the catarrhines. A spider monkey had a brain LDH pattern similar to that of the ceboids shown in Fig. 2. However, two capuchin monkeys had an *H* LDH of slower mobility. Furthermore, one of the two titi monkeys may well have been heterozygous at the genetic locus for *M* LDH, since the LDH of this monkey showed five separate electrophoretic components in band 5, four in band 4, three in band 3, and two in band 2. The most important difference between the ceboid group and the catarrhine group was the larger quantity of *M* LDH in the ceboid brains than in the catarrhine brains. The intensity of staining in

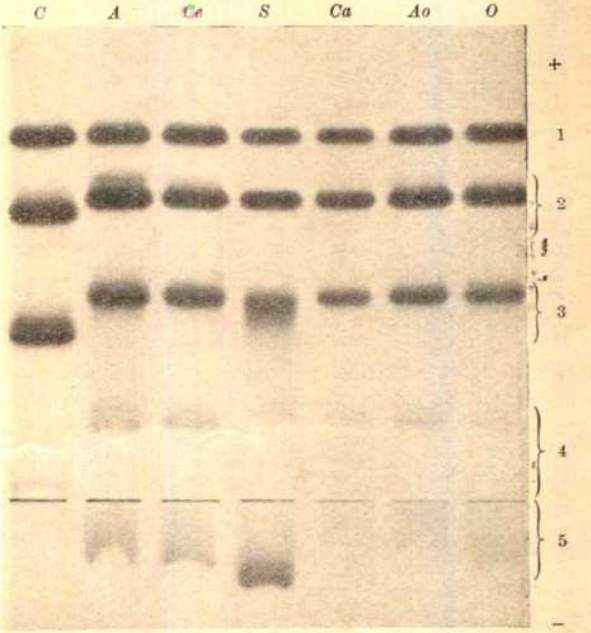

Fig. 2. Brain LDH patterns of *Cercopithecus aethiops* (*C*), *Alouatta* (*A*), *Cebus* (*Ce*), *Saimiri sciureus* (*S*), *Callicebus* (*Ca*), *Aotes trivirgatus* (*Ao*), and *Oedipomidas oedipus* (*O*)

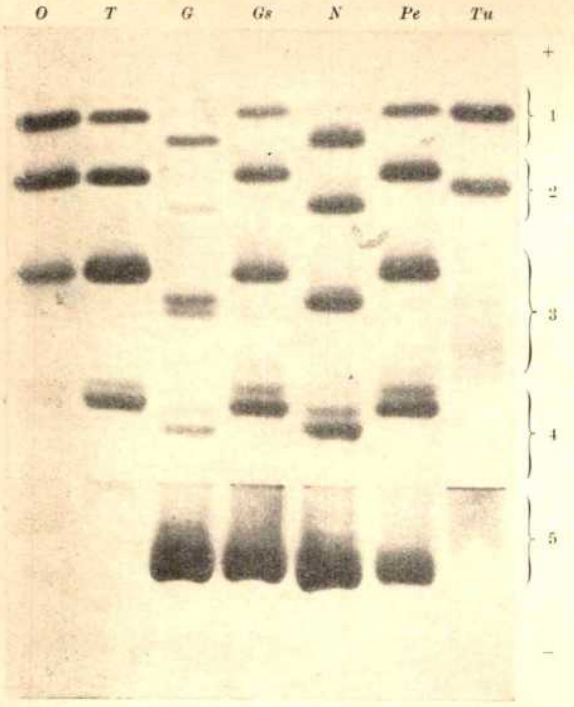

Fig. 3. Brain LDH patterns of *Oedipomidas oedipus* (*O*), *Tarsius syrichta* (*T*), *Galago crassicaudatus* (*G*), *Galago senegalensis* (*Gs*), *Nycticebus coucang* (*N*), *Perodicticus potto* (*Pe*), and *Tupaia glis* (*Tu*)

bands 4 and 5 was distinctly higher in the ceboids. Nevertheless, *H* LDH still predominated over *M* LDH in the ceboid brains.

Fig. 3 extends the comparisons of the brain LDH patterns from the Anthropoidea or sub-order of higher primates (represented by the cotton-top marmoset) to the more distant primate relatives of man (represented by the tarsier and different lorisoids, and also the tree shrew). The tarsier pattern was similar to the ceboid pattern in the mobilities of the LDH bands as well as in the greater proportion *H* enzyme to *M* enzyme in the brain. However, in the tarsier pattern, band 4 stained as intensely as band 1, whereas in the ceboid pattern band 4 did not stain so heavily as band 1. Thus, the proportion of *H* to *M* appeared to be somewhat less in the tarsier brains than in the ceboid brains. Among the Lorisoidea, the lesser bush-baby and *potto* had LDH bands with the same mobilities as those of the tarsier and most of the ceboids, while the greater bush-baby and slow loris had an *H* LDH of slower mobility. All members of the Lorisoidea had much larger amounts of band 5 than band 1 in their brains. Thus the lorisoids, in contrast to the other primates, had much more *M* enzyme than *H* enzyme in their brains. *Tupaia glis* of the Tupaiodea, a group long separated from other placental mammals and not regarded by all authorities as members of the order Primates[10], showed a preponderance of the *H* enzyme in their brains. Thus the LDH pattern of the tree-shrew was like that of the higher primates rather than the lorisoids. On the other hand, the African hedgehog, *Atelerix*, and the masked shrew, *Sorex cinereus* (representing the oldest order of placental mammals, the Insectivora), were also examined, and their brains were rich in *M* LDH.

Just as the overlap of the midbrain by an enlarged cerebrum occurred independently and to different degrees in different lineages of placental mammals during the Tertiary epoch[11], the biochemical evolution of the brain must also have progressed independently in these lineages. Thus the tree-shrew results need not deter us from deducing from the lorisoid, tarsier, ceboid, and catarrhine results that a shift in brain metabolism from synthesis of a preponderance of muscle-type to heart-type lactic dehydrogenase occurred in the evolutionary development of man. The lorisoid results suggest that man's primate ancestors at the beginning of the Tertiary epoch still had in their brains the form of lactic dehydrogenase which is best suited for anaerobic energy metabolism.

This work was supported by research grants from the U.S. Public Health Service (*MY* 2476) and the National Science Foundation (*GB*–1241). We thank Dr. Cyrus Stimson (staff physician of Plymouth State Home and Training School) for providing the human tissues, Dr. Arthur J. Riopelle (director of the Delta Regional Primate Research Center) for the ape tissues, and Dr. Galo B. Ocampo (director of the National Museum of the Philippines) for the tarsiers. We also thank Mr. Hak Suk Yoon for his assistance and Dr. Gabriel W. Lasker for his advice.

MICROBIOLOGY

Stability of β-Galactosidase in Starved *Escherichia coli*

The endogenous metabolism of micro-organisms in aqueous suspension in the absence of added nutrients may involve the utilization of endogenous protein and RNA[1], as well as amino-acid pool constituents and reserve substances such as glycogen and polyhydroxybutyric acid (see reviews by Dawes and Ribbons[2]). Investigations

Table 1. Changes in Dry Weight, Viability, Protein and Induced β-Galactosidase Activity in *Escherichia coli* starved in Aerated Saline Phosphate Buffer (*p*H 6·5) at 37°

Bacteria were grown and starved as described in the text. β-Galactosidase activity is expressed as μmoles *O*-nitrophenylgalactoside hydrolysed/h/mg initial dry weight bacteria at 37° in sodium phosphate buffer (0·2 N Na^+, *p*H 7·2).

with *Aerobacter aerogenes*[1], *Escherichia coli* and *Pseudomonas fluorescens* have shown that starvation in aerated saline buffer at 37° results in a considerable loss of protein during a period when viability of the populations remains at 95–100 per cent. Since analyses of ultracentrifugal fractions separated from *A. aerogenes* after various periods of starvation showed decreases in the protein content of the insoluble, ribosomal and soluble fractions[3], the loss apparently represents a depletion of various cell proteins. It is interesting, therefore, that induced β-galactosidase in *Escherichia coli* was found to be relatively stable while other proteins were being rapidly degraded during turnover[4]. The relative stability of induced β-galactosidase in a wild-type strain of *E. coli* during starvation has been investigated and this communication records the relevant data.

Escherichia coli (M.R.E. 162: from human faeces) was grown at 37° for 16 h in shaken flasks (2 l.) containing a defined ammonium-salts medium[1] (100 ml.) with lactose (1 per cent w/v) as the sole source of carbon. Stationary phase organisms were separated from the culture and washed twice with saline phosphate buffer (0·055 M NaCl and KH_2PO_4 + K_2HPO_4 (0·01 M PO_4), *p*H 6·5) by centrifugation. The β-galactosidase concentration in these bacteria was about 90 units whereas bacteria grown in a medium with mannitol as the sole source of carbon contained less than 0·2 units of enzyme. The bacteria were re-suspended (1·5–2·5 mg dry weight/ml.) in saline buffer and the suspension was aerated with washed air in a Dreschel bottle at 37°; effluent air escaped through a water reflux condenser fitted with an air filter. At intervals samples were removed for determinations of total protein by a Biuret method[5] (colour obeyed Beer's law in the range used; coefficient of variation, 1·1 per cent for fifteen replicates), β-galactosidase with *O*-nitrophenylgalactoside[6] (*O*-nitrophenol colour obeyed Beer's law; coefficient of variation, 2·6 per cent for twenty-two replicates), viability by viable plate count (coefficient of variation, 4 per cent for twelve replicates with mean count of 835 colonies) and viability by slide culture[7] (coefficient of variation, 1 per cent for twelve replicates with mean of 95·7 per cent). The enriched agar medium for viable counts and slide culture was as described by Postgate, Crumpton and Hunter[7] except that glucose (0·5 per cent w/v) replaced glycerol.

The results (Table 1) show that during 30 h at 37°, when loss of viability was 5 per cent, losses of total protein and β-galactosidase activity were 21 and 29 per cent of the initial concentrations, respectively; the total protein-loss accounted for 56 per cent of the dry-weight loss and one of the products was ammonia. When starvation was continued for 48 h, further small losses of total protein and galactosidase activity occurred accompanied by a further small loss of viability. At each time-interval, β-galactosidase was determined in the whole suspension and in the bacteria separated by centrifugation, and re-suspended in saline buffer; under the latter conditions results were slightly lower in some cases due, perhaps, to incomplete recovery of bacteria or failure to re-suspend to exactly the same volume. When bacteria were starved in saline buffer containing thiomethylgalactoside[8] (TMG; 1 mM), β-galactosidase activity remained at the initial level for at least 24 h, while loss of protein was similar to that in the absence of inducer.

Thus, while under some conditions, β-galactosidase and indeed other induced enzymes in non-growing bacte may be relatively stable (see ref. 4), the present res indicate that in the absence of nitrogen and c sources at growth temperature, induced β- activity in *E. coli* is lost at a higher rate th rate of degradation of all cellular prote according to two methods of assay, was level that excludes bacterial lysis as t of protein or β-galactosidase activ

of *A. aerogenes* after various periods of starvation, by the present method, and by a copper-iodometric α-amino nitrogen method (after hydrolysis of the bacteria with 6 N hydrochloric acid for 20 h at 105°), gave similar results for protein losses. The stabilizing effect of TMG on β-galactosidase in starved *E. coli* may be due to the formation of a stable inducer-enzyme complex or to resynthesis of enzyme stimulated by the inducer.

VIROLOGY

A Cytopathogenic Virus from the Brain of Fowl

A virus has been isolated from the brains of chickens which have died or been killed while suffering from a disease indistinguishable by clinical signs or histopathological lesions from infectious avian encephalomyelitis ('epidemic tremor').

The virus has multiplied in monkey kidney cell culture and has been repeatedly passaged in that system, in which it produces a cytopathic effect similar to that produced by an enterovirus. The agent appears to be completely resistant to the effect of ether. An antiserum produced against the Van Roekel strain of infectious avian encephalomyelitis virus has been shown to have a neutralizing effect against this virus in monkey kidney cell culture.

Further investigations of the virus are in progress, the results of which will be published in the near future.

GENETICS

Evolution of Over-dominance during the Initial Spread of New Alleles

Bodmer and Parsons[1–3] have discussed a model for the initial increase in the frequency of newly arising, favourable mutations in a large undivided population and under different mating systems. They argued that over-dominance (higher fitness of heterozygotes over the [illegible]) has evolved in outbreeding species during [illegible] follows: (1) a new allele, say A_1, at locus [illegible]ally in the heterozygotes when it is [illegible]y in the population; (2) selection [illegible]te of increase in [illegible]at primarily [illegible] linked, [illegible]d

solutions for the conditions and relative rates of gene frequency changes under one- and two-locus models. The crucial feature (3 above) of their theory has not yet been established quantitatively. In fact, some calculations by Haldane[6] on the postulated role of dominance modifiers suggest that allelic substitution occurs largely through selective forces operating on the primary locus rather than through modifiers. These ideas are rather easily checked by simulation on a digital computer. This communication briefly re-examines the arguments involved in the theory of evolution of over-dominance with the help of exact numerical solutions obtained by simulation.

Following Bodmer and Parsons[1], consider first a model in which a new allele A_1 is introduced at a low frequency in an A_2A_2 population. Given the initial frequencies p^2 (A_1A_1), $2pq$ (A_1A_2), q^2 (A_2A_2), and their relative selective values, a, h, b, respectively, the frequency of A_1 in the following generation is:

$$p' = \frac{ap^2 + hpq}{ap^2 + 2hpq + bq^2};$$

the condition for increase in p is simply that $p' > p$. Ignoring terms involving p^2, this requires $h > b$, and thus, the authors concluded that "the heterozygotes must be superior in fitness to the original wild homozygote . . . since the frequency of the homozygotes A_2A_2 is of the second order in p, its viability does not affect the final progress". However, it can be easily shown that over-dominance is not a necessary condition and that the selective value of A_2A_2 is important in terms of the relative rates of change in p. Consider the condition for increase in p under the following situations: (1) no dominance:

$$(a = 1 + x,\ h = 1,\ b = 1 - x),\ p'/p = 1 + \frac{xq}{1 + x(p - q)}$$

(2) allele A_1 recessive:

$$(a = 1 + x,\ h = b = 1),\ p'/p = 1 + \frac{xpq}{1 + xp^2}$$

(3) over-dominance:

$$(a = b = 1 - x,\ h = 1),\ p'/p = 1 + \frac{x(p^2 + q^2 - p)}{1 - x(p^2 + q^2)}$$

(4) under-dominance:

$$(a = 1 + x + y,\ h = 1,\ b = 1 + x),$$

$$p'/p = 1 + \frac{p(x + y) - x(p^2 + q^2) - yp^2}{1 + x(p^2 + q^2) + yp^2},$$

so that for $p' > p$,

$$y > \frac{x(p^2 + q^2 - p)}{pq}.$$

In cases (1–3), clearly $p'/p > 1$, or $p' > p$ (since $x > 0$), and also in case of (4), this condition is satisfied with an appropriate value of y.

Table 1 gives a few numerical examples of the relative rates of initial progress in the frequency of A_1 under random mating versus varying proportions of mixed selfing and random mating. Clearly, all three selective values (a, h, b) influence the changes in gene frequency and note that under random mating, even under-dominance would allow an increase in p, given appropriate initial p and a large enough value of $y(= a - b)$. Bodmer and Parsons[1] imply that this could occur only under inbreeding, in contrast to the random mating situation in which "heterozygote advantage is a pre-requisite for a new gene to increase in frequency". On the other hand, they ruled out any role of over-dominant loci under inbreeding where, in fact, the difference in the selective values of two homozygotes (a–b) is very restrictive in terms of the long-term maintenance of polymorphic loci unless there is involved substantial heterozygote advantage[7,8].

The relative rates of initial increase in the frequency of allele A_1 are also relevant to the calculations of the cost of such a substitutional process, since, as shown by Haldane[9], the total cumulative load is influenced by the degree of dominance and the breeding system. Haldane's method was criticized by Bodmer[3], who considered the proportion of $AA : Aa$ more relevant than the relative proportions of all three genotypes. However, the numerical results given in Table 2 show that Haldane's calculations are essentially correct; inbreeding reduces the cost of allelic substitution by a favourable gene proportionately more with under-dominance or no dominance than with partial or complete dominance. It should be emphasized, however, that instead of the total cost, the cost incurred per generation is more important as a measure of loss in the reproductive potential, especially in view of the different rates of change in gene frequencies. The cost per generation involved in this selective process is indeed nearly the same for various proportions of selfing(s) although it varies in relation to the allelic frequency of A_1 in different ranges. It should also be noted that introducing recurrent mutation rates in the model only slightly changes these cost figures.

Using a two-locus model, Bodmer and Parsons[5] showed that "a modifier B the only effect of which is to enhance the heterozygote advantage of Aa will only be selected if it is sufficiently closely linked to locus A–a". The example they used to illustrate the effect of linkage on such a mechanism for the evolution of over-dominance assumed

ab/ab to be the prevailing genotype and gametes *AB* and *Ab* to be in very low initial frequencies. The relative viabilities were: *ab/ab*, 1·0; *Ab/ab*, 1·05; and *AB/ab*, 1·15 (other viabilities were not specified). Such a model is clearly inadequate to illustrate the evolution of over-dominance through selection for modifiers since over-dominance at locus *A–a* is assumed to begin with. Let us consider a more pertinent model similar to the one discussed by Haldane[6] in which a dominant allele *M* modifies the fitness of *Aa* genotype such that the relative selective values are:

$$\begin{array}{c} \\ AA \\ Aa \\ aa \end{array} \begin{array}{c} \begin{array}{ccc} MM & Mm & mm \end{array} \\ \begin{pmatrix} 1 & 1 & 1 \\ 1-\alpha\lambda K & 1-\alpha\lambda K & 1-\lambda K \\ 1-K & 1-K & 1-K \end{pmatrix} \end{array}$$

Here, λ measures the degree of dominance (namely, $\lambda = 0$, allele *A* dominant; $\lambda = 1$, allele *a* dominant; $\lambda = 0{\cdot}5$, no dominance, etc.), and K determines the selection intensity at locus *A–a*. Let the loci *A* and *M* be linked with recombination value, *c*. A large number of computer runs were made to determine the relative effects of λ, α and K with different initial frequencies of alleles *A* and *M*. Table 3 gives a sample of the results obtained for the case of random mating and recombination value $c = 0{\cdot}001$, in combination with other parametric values. Points to note are: (1) the frequency of allele *A* increased rather rapidly with large values of K and the relative rates of this increase varied with λ and the initial p_A, irrespective of the modifier effect, α; (2) the frequency of modifier *M* increased in frequency with $\alpha = 0$ or $-0{\cdot}25$; this follows from the fact that $\alpha \leqslant 0$ gives allele *M* an advantage over *m* in combination with *Aa* and due to linkage disequilibrium, genotypes *AaMM*, *AaMm* occurred at a higher frequency than *Aamm* individuals; (3) thus, modifier frequency did not seem to influence the rate of initial spread of allele *A* (Compare the values of p_M for $\lambda = 0{\cdot}25$ and 0·50, Table 3) which is largely determined by the selection parameters K and λ, as pointed out earlier by Haldane[6]. In fact, with $c = 0{\cdot}50$ (no linkage), it was found that the frequency of modifier *M* did not increase significantly in any case and yet the values of p increased slightly at higher rates than those observed with linkage.

It therefore seems unlikely that over-dominance has evolved through the accumulation of linked modifiers during the initial spread of a newly arising favourable allele as postulated by Bodmer and Parsons. The role of over-dominance in the maintenance of stable polymorphism at linked, interacting loci is, however, a different matter, as shown by Kimura[10]. Investigations by simulation of wide variety of selection models showed that in models without intrinsic over-dominance (for example, optimum model) linkage disequilibria result in some marginal over-dominance which is a necessary condition for the stability of gene frequency equilibria[11]. The initial increase in frequency of any rare allele would be inevitable in a large population if there is a stable non-trivial peak in the neighbourhood. The effects of selection, mating system, linkage and the nature and stability of resulting gene frequency equlilibria must be analysed jointly, if we are to understand the evolutionary properties of over-dominant linked gene complexes.

VETERINARY SCIENCE

Adaptation of Bovine Sweat Glands to a Hot Environment

THE increase in human sweating following acclimatization to heat is well known[1]. Bianca[2] found that, with cattle, repeated exposure to heat (37° C) in a psychrometric laboratory resulted in a progressive reduction in body temperature, respiratory rate and heart rate. However, there is little evidence of any causal adjustment of sweat gland activity under these conditions. Experiments by McLean[3] and Banerjee *et al.*[4] suggest that the sweating rates of cattle under artificial heating are directly related to the prevailing temperatures animals have been previously exposed to.

To determine any possible acclimatization of sweat gland production to heat, two 17-month-old bulls were transferred from a warm (Armidale, 30° 30′ S., 151° 35′ E., 3,333 ft. altitude) to a hot (Moree, 29° 20′ S., 150° 0′ E., 700 ft. altitude) environment. One of the animals was a pure-bred Hereford, the other was a ¾ Santa Gertrudis–¼ Shorthorn. The animals were transferred from Armidale to Moree on February 26, 1963, and remained at Moree for 4 weeks. Mean monthly maximum and minimum temperatures for Armidale in February were 82° and 58° F respectively, while the corresponding figures for Moree in March were 91° and 67° F.

Sweating rate from the back thoracic[3] region was measured using the ventilated capsule technique[6], rectal temperature by a clinical thermometer, respiratory rate by counting flank movements and skin temperature with a copper-constantan thermocouple. Two days of observations are reported. Days I and II refer to data collected after the animals had been at Moree for one day and four weeks respectively. On each of the two days, observations were made between 10 a.m. and 3 p.m. while the animals were exposed to direct solar radiation. Mean dry bulb temperatures on days I and II were 90° and 89° F respectively.

Table 1. Mean Physiological Responses of the Hereford and the ¾ Santa Gertrudis before and after the Four-week Acclimatization Period at Moree

Observation	Hereford		¾ Santa Gertrudis	
	Day I	Day II	Day I	Day II
Rectal temp. (° F)	102·5 ± 0·7	102·3 ± 0·2	101·8 ± 0·3	101·8 ± 0·2
Respiratory rate (No./min)	94 ± 19	69 ± 11	65 ± 8	52 ± 7
Sweating rate (mg/31·8 cm²/5 min)	129 ± 32	141 ± 37	165 ± 18	150 ± 24
Skin temp. (° C)	39 5 ± 2·1	35 8 ± 1·6	38·9 ± 1·4	35·9 ± 1·1

Of the two animals, the ¾ Santa Gertrudis was least affected by the higher temperatures encountered at Moree on day I, this being demonstrated by its lower rectal temperature, respiratory rate and skin temperature (see Table 1). After the 4-week acclimatization period (day II) both animals recorded marked reductions in respiratory rate and skin temperature, while rectal temperature showed little change.

As illustrated in Fig. 1*a*, the sweating rates of the animals on day I followed a similar but rather irregular pattern of response. Compared with maximum sweating rates obtained previously at Armidale[6] (¾ Santa Gertrudis 158, and Hereford, 157 mg/31·8 cm²/5 min), only the ¾ Santa Gertrudis showed any increase in sweat gland activity. On day II (Fig. 1*b*) the sweating rates of both animals followed a definite trend with maximum rates occurring about midday. This was similar to the pattern observed earlier at Armidale except that the range of sweating rates was greater at Moree (76–184, compare 122–158 mg/31·8 cm²/5 min).

This experiment shows that although the diurnal pattern of sweat production in cattle of both the types *Bos indicus* and *Bos taurus* can be altered by a sudden transfer to a hotter environment, only the sweat glands of the former are capable of increased secretion. Furthermore, the pattern of sweat production after the animals became acclimated to the Moree environment provides further[7] indirect evidence of the importance of direct solar radiation in the control of sweat gland secretion.

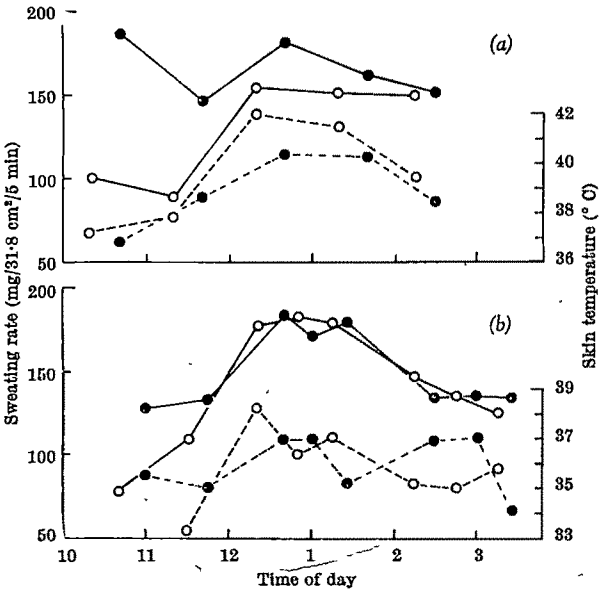

Fig. 1. Sweating rates and skin temperatures of the Hereford and ¾ Santa Gertrudis on days I (*a*) and II (*b*) at Moree. Hereford: sweat (O—O); skin temperature (O - - - O). ¾ Santa Gertrudis: sweat (●—●); skin temperature (● - - - ●)

PSYCHOLOGY

Effect of Previous Exploratory Activity on the Exploration of a Simple Maze

There has been a good deal of discussion about the nature of the motivation involved in exploratory behaviour, and various theories have been put forward[1–3]. Most such theories suppose that this motivation is aroused directly by novel stimuli, and therefore that the strength of the motivation is relatively immune to deprivation effects. On the whole the experimental evidence bears out this view, though what may possibly be a deprivation effect has been found with visual exploration in monkeys[4]. Another type of test has not, however, been used. If we wish to examine a motivation such as hunger we can vary the period of deprivation and see how this affects the subsequent behaviour; alternatively we can use a fixed period of deprivation, give the animals varying amounts to eat, and see whether this appears to alter drive level. The first procedure has been attempted in the exploratory case with negative results (in rats at least)[5]; the second procedure has not. If the motivation involved 'builds up' in the rat when it is not exploring and is reduced by exploration, then exploration of one environment should reduce the motivation and so reduce the amount of exploration, immediately afterwards, of another quite different environment. If, on the other hand, the motivation is aroused primarily by the stimuli in the environment, then exploration of one environment should not reduce subsequent exploration of another dissimilar environment.

The subjects in this experiment were twenty-four satiated female hooded rats about 100 days old. They were given three days of pretraining in which they were allowed to move around a table-top for a few minutes and were picked up and handled a number of times. The animals were then randomly assigned to three groups of eight animals each. On the fourth day the animals in Group I were given exploration for 3 min in an elevated Y-maze, with arms 18 in. long, 4 in. wide and 18 in. high; they were removed from the Y-maze, kept in a small delay cage for 0·75 min and then allowed to explore an enclosed T-maze for 2 min. The plan of this maze is given in Fig. 1; the walls were 6 in. high and of unpainted metal. The animals in Group II had 3 min exploration of an open field 3 ft. × 3 ft., with 2 ft. high dark green and white striped walls; they were then kept in the delay cage for 0·75 min and allowed to explore the enclosed T-maze for 2 min. The animals in Group III were put directly into the delay cage for 0·75 min and then allowed to explore the T-maze for 2 min. The activity of the rats was recorded in terms of 'section entries' during each 30 sec of exploration. In the elevated Y-maze each arm was divided into two imaginary 9-in. 'sections'; in the open field the 'sections' were nine, 1 ft. × 1 ft., squares marked on the floor; the 'sections' in the T-maze are shown by the dotted lines in Fig. 1. A rat was considered to have

entered a section if its head and three of its paws were over the dividing line.

The results in terms of section entries are shown in Fig. 2. The decline in activity between the first and last minutes of the first trial for Groups I and II is characteristic of this type of situation and is in each case highly significant ($P < 0.008$, signs test). It is clear from the graph that there is no appreciable difference between the groups on the second trial. The decline between the first and second minutes of the second trial is significant at below the 0·008 level for Group I and Group II and at the 0·07 level for Group III (two tailed signs tests). There are no significant differences in activity between the three groups individually either overall or in any 30-sec period, but Groups I and II combined are slightly more active than Group III in the first 30 sec of the second trial ($P = 0.05$ signs test).

It appears, therefore, that after a rat has explored one type of environment, and has to some degree reduced the capacity of that environment to evoke exploration, it is just as exploratory in a new environment as a rat with no immediately preceding exploratory experience. The slight difference between the groups in the first 30 sec of the second trial is, of course, in the wrong direction for any view which predicts that previous exploratory activity has a depressing effect on subsequent exploration. It may perhaps be due to some sort of 'warm up' effect, but is too slight to merit much discussion. In this type of situation at least, the motivation for exploratory behaviour seems, therefore, to be aroused by the stimuli in the environment, rather than to be present in the animal, perhaps as a result of 'deprivation', and reduced by exploratory experience. In this respect, at least, this motivation is therefore more analogous to such externally aroused drives as fear than to hunger or thirst.

I thank Mr. A. J. Watson for his advice.

The work was carried out in the Department of Experimental Psychology, University of Cambridge, and supported by a training in research grant from the Medical Research Council.

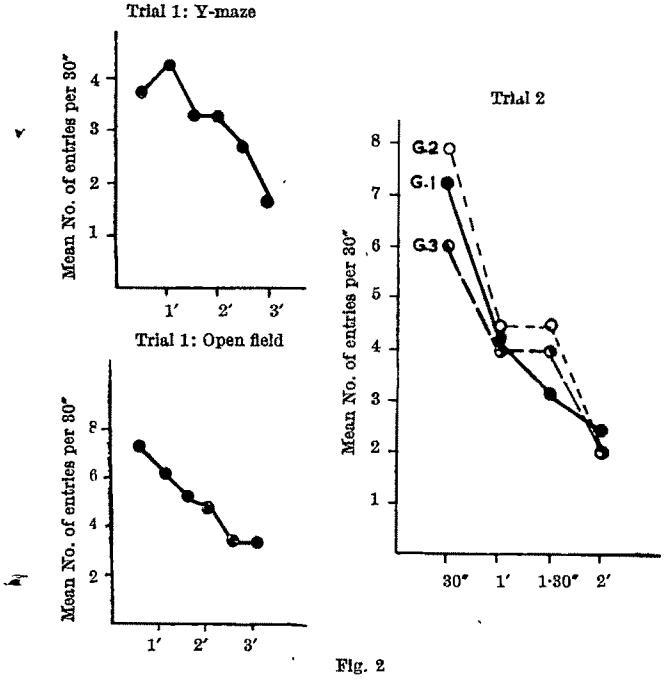

Fig. 2

Time Contraction and Psychomotor Performance produced by 'Psilocybin'

It is particularly rewarding to investigate the experience of chronosystole, or time contraction during sympathetic excitation, as this state, which is connected with an increase in metabolic rate, can be elicited at will through psychotomimetic, pyretogenic drugs such as mescaline, marihuana, D-lysergic acid diethylamide (LSD), 'Psilocybin'[1,2]. We may define time contraction in terms of an alteration in the signal per noise ratio of the sensor, or in an adaptation of Stroud's[3] terminology, an increase in data content. In short, if more events are happening within a chronological time unit, the phenomenon of time contraction is experienced. Hofmann's self-observation, in what may be called the first description of time contraction after a dose of 0·25 mg of LSD (ref. 4), relates "the impression of being unable to move from the spot" on his way home from the laboratory on a bicycle. Delay's[5] systematic description of the psychic effects elicited by 'Psilocybin' also refers to experiences which may be considered phenomena of time contraction: "J'ai l'impression que le temps passe plus lentement, qu'il a plus de densité". "Tout est d'une longuer indéfinissable."

Within the framework of space–time equivalence, time contraction can be illustrated through the concomitant expansion of space; specifically, by the increased size of handwriting samples at the peak of the psychotomimetic drug experience[2]. When finger-tapping rates are used as a measure of intensification of time, the magnitude of the drug reaction may be assessed in relation to the control value, the baseline of a subject. (See in this connexion Wilder's[6] law of initial values.) Therefore, patients in various states of excitation and depression cannot be expected to experience changes in time perception analogous to those of an average healthy subject, that is, the patient's experience of time contraction may be different in degree or may not occur at all. (This explains the divergent results of Kenna and Sedman[7].)

Among the various attempts to define 'Psilocybin' reactivity, the most notable is that of Isbell[8], who found a close correspondence between the maximum effect of various drug doses on pupillary size and that on mental response. No effort has been made, however, to quantitatively differentiate the degrees of reactivity in subjects who have ingested the same dose of 'Psilocybin'. Long experience has shown us that a dose of 115 μg/kg 'Psilocybin' is likely to produce one of the following reaction types: 'non-reactors', 'mild reactors', 'reactors' and 'strong reactors'. Hence the problem presents itself of characterizing them with relatively simple, quantifiable parameters.

We have refined the use of two already existing variables for the measurement of time contraction—handwriting samples and finger-tapping rates. As shown by the following representative examples, the former proved useful for the characterization of 'strong reactors' and 'non-reactors', the latter for that of 'reactors' and 'mild reactors'.

Handwriting size can be quantified to measure the extent of psychomotor drug reactivity. A planimetric comparison of pen-and-ink handwriting samples on flat paper[9] reveals that whereas only 60·00 cm² is needed to cover the first five written lines for our 'strong reactor' under control conditions, 81·30 cm² is required at drug peak—an increase of 31 per cent (compare the upper and lower halves of Fig. 1). On the other hand, the handwriting space of a 'non-reactor' shows no increase at drug peak as compared with the control performance (see upper and lower halves of Fig. 2).

Table 1. Quantification of Time Contraction

Mean tapping rates and variances (at an 8-min period)

	At peak of 'Psilocybin' experience		Next day (control) at the same time	
	Mean	Variance	Mean	Variance
Subject *A* ('mild reactor')	2·21/sec	0·018	1·16/sec	,0 003
Subject *B* ('reactor')	1·31/sec	0 001	0·42/sec	0·001

Mean tapping rates and variances at drug peak, that is, 100 min after oral ingestion of the drug, were obtained using silent Morse-key tappings at a freely chosen speed during an 8-min period. These were also measured during a control period the following day. Afterwards, power density spectra were derived according to the procedure of Ralston and Wilf[11], using a 'Bendix' *G*-20 digital high-speed computer. (The results of spectral analysis are to be published[10].) The tabulated mean values of the fluctuations, and the variance in tapping rate for the 8-min periods for two subjects—a 'mild reactor' and a 'reactor'

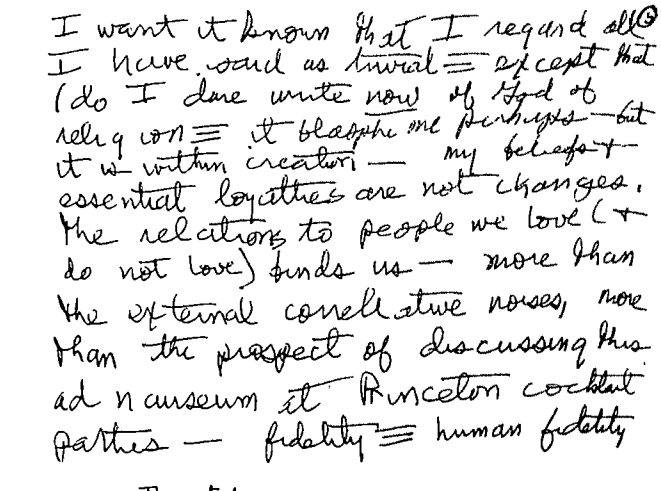

Fig. 1. Handwriting samples of a 'strong reactor' 2 h after the ingestion of 115 μg/kg 'Psilocybin' (upper portion of figure) as contrasted with control sample obtained on the following day (lower portion); half the original size

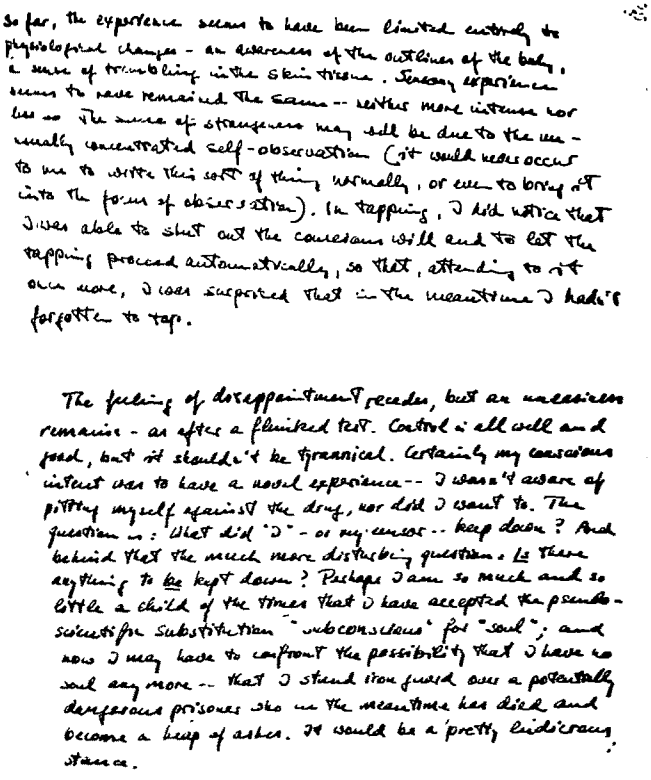

Fig. 2. Handwriting samples of a 'non-reactor' 2 h after the ingestion of 115 μg/kg 'Psilocybin' (upper portion of figure) as contrasted with control sample obtained on the following day (lower portion); half of the original size

—show that there is a significant increase in tapping rate at the peak of the 'Psilocybin' experience relative to the respective control value (see Table 1).

This increase also reflects the degree of the excitation syndrome which 'Psilocybin' can produce in an individual. It can be seen from Table 1 that subject *B* with a low mean control tapping rate (0·42/sec) and a low variance (0·001) increased his performance more than threefold at drug peak, whereas subject *A* with a high baseline (mean control tapping rate 1·16/sec) increased his performance not quite twofold at drug peak with a larger variance. This again indicates that the baseline (control value) of a subject is important in the assessment of his drug reactivity.

These investigations were supported in part by grant *M*-2927-*C*II of the National Institutes of Health, U.S. Public Health Service and the Comley Coleman Fund. We thank Dr. A. Mace, Dr. B. Pasamanick, Mrs. J. Goldner and Mr. S. M. England for their assistance. We also thank Drs. R. Bircher and L. B. Achor and Mr. H. D. Burt, of Sandoz Pharmaceuticals, Hanover, N.J., for a donation of 'Psilocybin'.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, January 24

INSTITUTE OF ACTUARIES (at Staple Inn, High Holborn, London, W.C.1), at 5 p.m.—Sir Paul Chambers, K.B.E., C.B., C.I.E.. "Problems in Forecasting in the Chemical Industry" (Twelfth Alfred Watson Memorial Lecture).

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. W. N. Aldridge. "Hydrolytic Enzymes and Their Inhibitors" (further lecture on January 31).*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. H. Ahmed, Mr. C. E. Maloney, Mr. J. D. Sankey and Mr. A. H. Beck: "Recent Studies of Dispenser Cathodes".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Colloquium on "Gaseous Insulation".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. M. W. Thring: "Towards a Creative Society: The Philosophy of Technology". (Second of three Cantor Lectures on "The Place of the Technologist in Modern Society".)

Tuesday, January 25

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Short Paper Meeting.

CAROLINE HASLETT MEMORIAL TRUST (at the Royal Commonwealth Society, Craven Street, London, W.C.2), at 5 p.m.—Mrs. Elizabeth Walker: "The Electrical Way of Life in Canada".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Use of Programmed Learning for Remedial Work in Higher Education" opened by Mr. D. Unwin and Mr. A. K. Spencer.

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. K. W. Pearson: "Method for the Prediction of the Fading Performance of a Multisection Microwave Link".

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. T. S. West: "Inorganic Trace Analysis" (Inaugural Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. Cotchin: "Tumours of Domestic Animals". (Fourth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation)*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Prof. P. L. Shinnie: "Problems of West African Archaeology".*

INSTITUTION OF MECHANICAL ENGINEERS, GRADUATES' AND STUDENTS' SECTION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. R. G. Croissant: "V.T.O.L. Aircraft".

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. W. R. Moore and Dr. B. M. Tidswell: "Instrumentation of Molecular Weight Measurements".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Eccleston Hotel, Eccleston Square, London, S.W.1), at 7 p.m.—Mr. D. Daniels: "Moulding Machinery Utilization and Unit Cost per Article".

Wednesday, January 26

CHALLENGER SOCIETY (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. H. L. Burstyn: "Foucault's Pendulum and the Progress of Oceanography".

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (at Imperial College of Science and Technology, London, S.W.7.), at 5 p.m.—Mr. P. M. Stocker: "The Integration of Man and Computer".*

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E./I.E.E. COMPUTER GROUPS (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Discussion on "The Linking of Computers" opened by Mr. T. Spinks and Mr. D. Rowland.

INSTITUTION OF ELECTRONICS AND RADIO ENGINEERS, TELEVISION GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Symposium on "The Problems of PAL in Relation to Receivers".

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. L. J. Clark: "The Carriage of Liquefied Petroleum Gases" (Thomas Lowe Gray Lecture).

SOCIETY OF ENVIRONMENTAL ENGINEERS, PACKAGING GROUP (in the Mechanical Engineering Department, Imperial College, Exhibition Road, London, S.W.7), at 6 p.m.—Mr. T. H. Carr: "Plastics Foams for Packaging".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. A. W. Taylor: "Problems in the Manufacture of Dehydrated Potato Flake"; Dr. T. P. Williams: "Chemistry of the Potato Cell Wall in Relation to Texture of Mashed Potatoes".

ASSOCIATION OF THE WILLIAM PENGELLY CAVE RESEARCH CENTRE WITH IMPERIAL COLLEGE CAVING CLUB (in the Department of Physics, Imperial College of Science and Technology, London, S.W.7), at 7.30 p.m.—Mr. Andrew Watson: "Bats in Caves".

Thursday, January 27

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. P. H. Kemp: "Sea and Shore".*

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 1.30 p.m.—Mr. Patric Dickinson: "Computer versus Creator" (last of three lectures).*

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. D. G. Deeks: "*D*-Region Electron Distributions in Middle Latitudes Deduced from the Reflexion of Long Radio Waves"; Mr. N. O. Weiss: "The Expulsion of Magnetic Flux by Eddies"; Mr. R. L. Parker: "Reconnexion of Lines of Force in Rotating Spheres and Cylinders".

INSTITUTION OF CIVIL ENGINEERS, HYDROLOGICAL GROUP (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Electrical Analogue Techniques in Ground Water Studies" introduced by Mr. J. A. Cole.

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. H. Noé and Mr. T. P. Flanagan: "Ionization Techniques Applied to Gas-Flow Measurement".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. C. Kao: "Optical Surface Waves".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. G. S. Dawes. "New Views on O_2, Transfer Across the Placenta". (Fifth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (in Lecture Theatre No. 1, Physics Building, Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Dr. Walter Marshall: "Investigations of Magnetic Materials Using Neutron Scattering. III. Neutron Investigation of Many Body Problems: Critical Phenomena in Magnetic Materials".*

SOCIETY FOR ANALYTICAL CHEMISTRY, AUTOMATIC METHODS GROUP (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Dr. A. W. Foster: "The Economics of Automatic Analysis".

Thursday, January 27—Friday, January 28

CHALLENGER SOCIETY, and REPRESENTATIVES FROM THE MARINE LABORATORIES (Natural Environment Research Council Scheme) (at the British Museum (Natural History), Cromwell Road, London, S.W.7), at 10 a.m. daily—Scientific Papers.

Friday, January 28

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 2 p.m.—Colloquium on "Microwave Noise-Measuring Techniques".

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Determination of the Geoid from Satellite Data". Speakers: Mr. D. G. King-Hele, Dr. R. R. Allan, Major-General R. C. A. Edge, Sir Harold Jeffreys, F.R.S., and Prof. S. K. Runcorn, F.R.S.

TELEVISION SOCIETY (in the Conference Suite I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. W. J. Morcom: "U.H.F. Translators".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Admiral of the Fleet, The Earl Mountbatten of Burma, K.G., P.C., O.M., D.Sc.: "Controlling the Information Explosion".

Saturday, January 29

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mrs. S. C. Coryndon: "African Faunas Past and Present".*

Monday, January 31

CIBA FOUNDATION FOR THE PROMOTION OF INTERNATIONAL CO-OPERATION IN MEDICAL AND CLINICAL RESEARCH (at The Royal Institute of British Architects, 66 Portland Place, London, W.1), at 5 p.m.—Prof. C. P. Leblond, F.R.S. (McGill University): "Role of the Golgi Complex in Secretion" (18th (Annual) Ciba Foundation Lecture).

UNIVERSITY OF LONDON (at the London School of Economics, Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. R. J. Harrison-Church: "Some Geographical Aspects of West African Development" (Inaugural Lecture).*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Colloquium on "The Problems of Radiation Pressure and Associated Mechanical Forces".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. F. Hoskins: "The Definition and Properties of the Delta Function".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. M. W. Thring: "The Status and Training of Engineers and Technologists". (Last of three Cantor Lectures on "The Place of the Technologist in Modern Society".)

PLASTICS INSTITUTE, LONDON SECTION REINFORCED PLASTICS SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. J. Kohn: "The Use of Balsa Wood in Association with Reinforced Plastics".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

EXPERIMENTAL OFFICER (preferably with a degree or equivalent qualification and experience in the field of electron optics) to assist in the operation of a high resolution electron microscope—The Registrar, Manchester College of Science and Technology, Sackville Street, Manchester, 1 (January 29)

ASSISTANT LECTURER (preferably with an interest in enzymology) IN BIOCHEMISTRY; a LECTURER and an ASSISTANT LECTURER (with an interest in electrochemistry) IN CHEMISTRY; and a LECTURER or ASSISTANT LECTURER IN PURE MATHEMATICS or APPLIED MATHEMATICS or MATHEMATICAL

STATISTICS—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (January 31).

LECTURER IN COMPUTER SCIENCE IN THE DEPARTMENT OF MATHEMATICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (January 31).

LECTURER or ASSISTANT LECTURER IN PHYSICAL CHEMISTRY—The Registrar, University College of Wales, Aberystwyth (January 31).

LECTURER (preferably candidate interested in metabolism) IN BIOCHEMISTRY IN THE RHEUMATISM RESEARCH CENTRE AND THE DEPARTMENT OF MEDICAL BIOCHEMISTRY—The Registrar, The University, Manchester, 13, quoting Ref. 235/65 (February 2).

LECTURER/ASSISTANT LECTURER IN THE DEPARTMENT OF MORAL PHILOSOPHY—The Secretary, The University, Aberdeen (February 5).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF APPLIED MATHEMATICS—The Registrar, The University, Liverpool, quoting Ref. CV/356 (February 5).

ASSISTANT LECTURER or LECTURER IN PSYCHOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (February 7).

LECTURER (with a good honours degree and subsequent research or industrial experience in the general field of electrical machines) IN THE DEPARTMENT OF ELECTRICAL AND ELECTRONIC ENGINEERING—The Registrar, The University, Leeds, 2 (February 7).

ASSISTANT PROFESSOR (with medical qualifications together with at least three years teaching experience and independent research interests, and preferably a knowledge of simple workshop practice) IN PHYSIOLOGY/PHARMACOLOGY IN THE INSTITUTE OF MEDICAL SCIENCE, Haile Selassie I University, Ethiopia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (February 10).

RESEARCH STUDENT (with a first- or second-class honours degree or an equivalent qualification, for example, G.R.I.C.) IN THE DEPARTMENT OF CHEMISTRY, to undertake research in high temperature inorganic chemistry, studying crystallization of oxide glasses, with a view to the degree of M.Sc. or the degree of Ph.D.—The Secretary, University of Aberdeen, Marischal College, Aberdeen, Scotland (February 11)

LECTURER (with a good degree in physiology, biochemistry, pharmacology, chemistry, medicine, or zoology, and postgraduate experience of Ph.D. or equivalent standard) IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY—The Deputy Secretary, The University, Southampton (February 12).

ASSISTANT LECTURER (man or woman graduate) IN PHYSICS—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (February 13).

LECTURER or ASSISTANT LECTURER (preferably with practical and/or research experience in structural analysis and in the design of both steel and reinforced concrete) IN THE DEPARTMENT OF CIVIL ENGINEERING—The Registrar, The University, Leeds, 2 (February 14).

LECTURER IN ENGINEERING MATHEMATICS (COMPUTATION)—The Secretary, The Queen's University, Belfast, Northern Ireland (February 15).

LECTURER or ASSISTANT LECTURER (with a degree in physics, chemistry, metallurgy or engineering, and postgraduate research experience in the field of structure and properties of materials) IN MATERIALS SCIENCE AND ENGINEERING—The Deputy Secretary, The University, Southampton (February 15).

ASSISTANT LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Hull (February 16).

LECTURERS (2) IN PSYCHOLOGY (an interest in social and/or educational psychology would be relevant to one of the posts) IN PSYCHOLOGY—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (February 26).

CHAIR OF PHYSIOLOGY AT MONASH UNIVERSITY, Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Registrar of the University, Clayton, Victoria, Australia (Australia and London, February 28).

DIRECTOR OF THE COMPUTER LABORATORY, University of Auckland, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, February 28)

LECTURER IN MEDICAL BIOLOGY at the University College of Rhodesia and Nyasaland, for duties which will include responsibility for the teaching of first-year medical students—The Inter-University Council, 33 Bedford Place, London, W.C.1 (February 28).

LECTURERS or ASSISTANT LECTURERS IN THE DEPARTMENT OF PHYSICS (for one post preference will be given to candidates with qualifications in theoretical physics) IN THE DEPARTMENT OF PHYSICS—The Registrar, The University, Leeds, 2 (February 28).

RESEARCH FELLOWS FOR INDEPENDENT RESEARCH—The Assistant Registrar (Room 28, O.R.B.), The University, Reading (February 28).

SENIOR RESEARCH FELLOW or RESEARCH FELLOW IN THE DEPARTMENT OF DEMOGRAPHY, Research School of Social Studies, Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 28).

ASSISTANT LECTURER or LECTURER (preferably with interests in structural geology and geophysics) IN THE DEPARTMENT OF GEOLOGY—The Deputy Secretary, The University, Southampton (March 1).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS (normally below the age of 30, with the degree of Ph.D. or equivalent research experience) IN CHEMISTRY, PHYSICS, METALLURGY, ENGINEERING, GEOLOGY, AGRICULTURAL SCIENCE OR RELATED SUBJECTS—The Registrar of the University of Wales, University Registry, Cathays Park, Cardiff (March 1).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS (preferably with the degree of Ph.D. or equivalent research experience, and normally below the age of 30) IN CHEMISTRY or PHYSICS—The Registrar, University of Keele, Keele, Staffs (March 1).

VETERINARY SURGEON to work on virus infections of domestic animals with special reference to the respiratory tract of the pig—The Secretary, Institute for Research on Animal Diseases, Agricultural Research Council, Compton, Berkshire (March 1).

ASSISTANT LECTURER IN GEOGRAPHY—The Registrar, The University, Hull.

BASIC GRADE SCIENTIFIC OFFICER (Bacteriology) (with an appropriate science degree) mainly for work in a routine laboratory—The House Governor, Bernhard Baron Memorial Research Laboratories, Queen Charlotte's Maternity Hospital, 339 Goldhawk Road, London, W.6.

ORGANIC CHEMISTS and PHYSICAL CHEMISTS (with a Ph.D., a good honours degree or H.N.C. qualification, and preferably under 30 years of age) for work which is in many cases of a fundamental nature and every encouragement is given to publish the results and study for a higher degree—The Director, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian.

PRE-DOCTORAL RESEARCH ASSISTANT to work on flat slab construction—Dr. J. C. Chapman, Civil Engineering Department, Imperial College of Science and Technology, London, S.W.7.

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (preferably with an honours degree in agriculture or in an appropriate biological subject) FOR THE DAIRY HUSBANDRY DEPARTMENT—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 66/T/1.

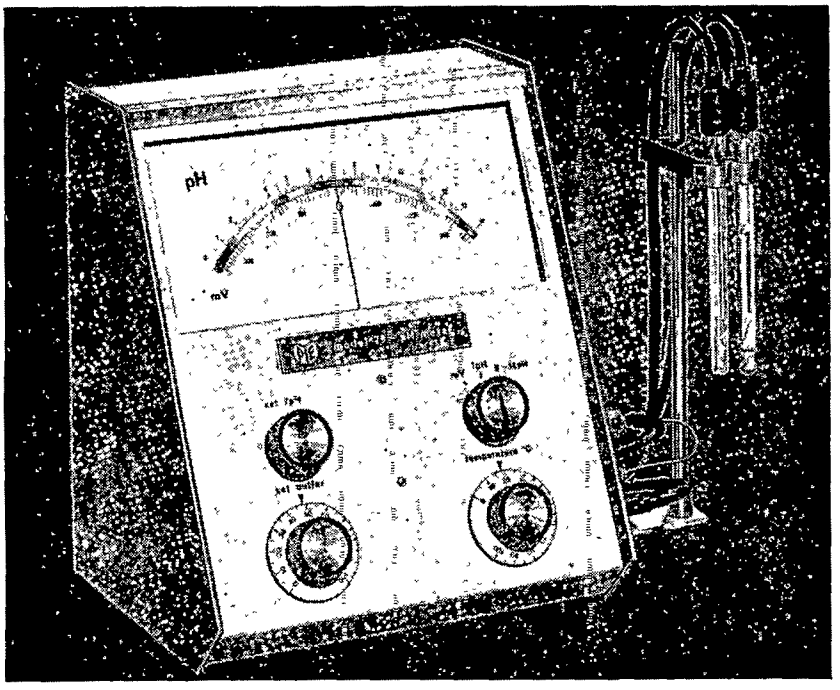
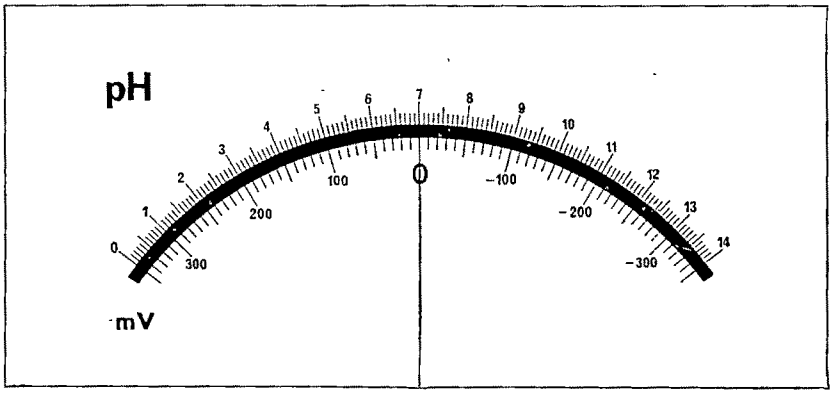
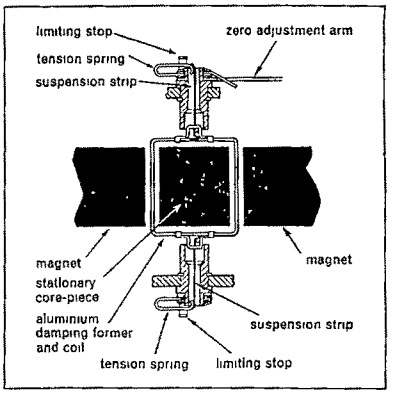
Pye model 79 pH meter



The Pye Model 79 pH Meter is a new instrument based on new principles. Moderate in cost and robust in construction, it provides exceptionally good accuracy and discrimination. It sets new standards in this class of measuring instrument for stability and freedom from effects of power supply variations.



Based upon the Pye taut band microammeter and a specially developed transistorised power stabiliser, the Model 79 represents a major advance in general purpose pH meter design.



Ranges of measurement are 0 to 14 pH or +350 to —350 mV which are covered on a 7 inch scale. With a precise millivolt measuring range, the Model 79 has many applications as a high impedance millivoltmeter.

Facilities are provided for both automatic and manual temperature compensation for slope and zero shift throughout the range of 0 to 100°C. A calibrated buffer control can be used to indicate electrode deterioration. An output of 5-0-5 mV is available for a potentiometric recorder.

The Model 79 represents exceptional value for the modern chemical laboratory. Please write for full details.

Accessories

The Model 79 is supplied with an integral electrode clamp and a Pye Ingold combined glass/reference electrode which has a measuring range of 0 to 13 pH, a temperature range of —5 to +70°C (intermittent use to 100°C) and an electrical null point of E_o7 for long-term stability. Additional accessories include a nickel resistance thermometer, a laboratory stand, a wide range of E_o7 electrodes, etc

Clear Scale

The fascia of the Model 79 is at an ideal viewing angle and parallax errors are eliminated by the knife-edge pointer and backing-mirror on the meter. These features, combined with bold and well-defined calibration on the unusually wide scale, enable readings to be taken to 0 02 pH without difficulty.

Taut Band Meter

Special features of the Pye taut band, or pivotless, panel meter are its invulnerability to damage by heavy electrical overloads and its remarkable freedom from mechanical hysteresis, friction, sticking and deterioration This gives very high sensitivity coupled with high accuracy and long term stability. The Pye suspension system employs strong incorrodible gold alloy strip

Send for descriptive brochure

SERAVAC LABORATORIES (PTY.) LTD.

Moneyrow Green, Holyport, Maidenhead, Berks., England.

Developments take place every day in statistics and mathematics, both in theory and practice. Information on any one of them, however, may well be published in a variety of scattered papers and other sources—usually difficult and time-taking to locate and assimilate.

GRIFFIN'S STATISTICAL MONOGRAPHS & COURSES

This Series is designed to present monographs on newly developed fields when such have become sufficiently important. It includes, also, courses of study in domains not covered by text books or where exhaustive treatment, even if practical, would be unnecessarily elaborate and expensive for the reader's needs.

The format is simple but robust and, for such a costly subject to print, the prices are moderate.

OVERSEAS AID IN ITS PROPER PERSPECTIVE

IN *The Decade of Development**—an address delivered in London on May 3, 1965, under the auspices of the Overseas Development Institute, and now published by the Institute—Miss Barbara Ward looks back over the first 5 years of the Decade, and emphasizes the numerous lessons learnt about the processes of development which could form a springboard for better action in the rest of the Decade. The whole idea of the United Nations' 'Decade of Development' lay in the belief that the development of the continents in the southern hemisphere could be so accelerated that 10 years would be a meaningful period for fundamental change.

In basic terms, it was visualized that the 3·5 per cent annual rate of growth in gross national product achieved by the southern developing countries in the 1950's could be increased to 5 per cent and, if possible, towards 6 per cent by the end of the Decade. It was also hoped that the share of these developing countries in world trade would increase from 26 per cent to 28 per cent, and that the terms of trade (which, after the end of the post-Korean War boom, had moved rather sharply against the primary producing countries) might move back, if not by the whole 12 points lost, then at least by 8. Finally, it was hoped that the developed countries, defined by some such criterion of national income as 700 dollars *per capita* per annum, would aim by the middle of the 'Decade of Development' to be giving 1 per cent of their national income in economic assistance. There was equal emphasis on aid and trade.

At the end of the 5 years, however, the gap between the richer and the poorer nations is greater still—not because the poor have necessarily grown poorer, but because the rich have become disproportionately richer. In most of the developed countries around the North Atlantic, the annual growth rate has risen from about 5 per cent to 6 per cent. Moreover, the relative shares in world trade have not improved, not because the trade of the developing world has not increased, but because the share of the developed countries, and of their trade with each other (which constitutes more than 70 per cent of world trade), has increased even more. In proportion to their national income, moreover, the assistance given by the wealthier countries has begun to fall; with the notable exception of France, these countries give considerably less than 1 per cent of their national income. This percentage is at the moment tending to fall even further, and with the exception of those countries which have been growing at phenomenal rates of more than 7 per cent *per capita* per annum (such as Greece, Taiwan or Israel) the world in the mid-'sixties has made no progress in lessening the gap between north and south.

Against this, Miss Ward suggests that a much more judicious estimate of the difficulties in the way of development is replacing the old optimism of 'development in a decade': we now have a sense of 'development in half a century'. The relative lack of progress over the past 5 years is not necessarily a cause for discouragement, but Miss Ward insists that there is need for much more analysis, for more and better designed strategies and for a great deal more determination. She points out that colonial and semi-colonial dependence has itself hindered more rapid development. Almost to the very end of the colonial period, local leaders were in no position to make decisions; yet in any process of development there must be a power to make decisions to deal with blocks and barriers which are not overcome by the sheer momentum of the actual economic process.

Beyond this, there are the differing consequences of different sequences of cause and effect. Here Miss Ward emphasizes that, while one of the real achievements of the past 20 years in the developing world has been an increase in life-expectancy from 25 to 45 years, this has resulted in a population growth far in advance of any possible modernization of the economy. With the possible exception of Liberia, censuses held under United Nations auspices in developing countries since 1960 have shown that populations were higher and rates of expansion more rapid than expected. Growth of population, moreover, occurring after a breakthrough into greater mechanization and productivity, acts as a spur to further growth; if population expands ahead of productivity without such a breakthrough, the outlook is very different. To introduce the full technology of modernization in farming and industry requires greater saving, but an ever-increasing population living longer pushes up consumption at the expense of saving; it is important to remember that because industry was developed first, and health later, the Atlantic nations were spared the profound dilemma that confronts the developing world to-day.

Next, Miss Ward makes a point which has been repeatedly emphasized by Prof. P. M. S. Blackett and others, namely, that technology, despite its predominant role in the world of to-day, is not always appropriate to the needs of the developing countries. The whole weight of economic research and of investment in further research is virtually confined to the developed countries, and for more than 50 years has taken the form of a search for labour-saving methods of production, with the consequent substitution of machines for man-power. Large-scale labour-saving technologies at this stage of development, however, constitute the least suitable methods of production for continents such as Asia, where the one abundant resource is labour, or for countries, like many in Africa, in which the one potentially competitive resource is labour, which is still relatively cheap.

Policies which seek to promote the introduction of advanced industrial technology into countries where there is neither the market nor the skills, nor the managerial capacity or other pre-conditions for such a technology to work successfully, constitute a block in the way of development, and do little to improve economic relations between the northern and the southern hemispheres. Moreover, the disproportion in technology spills over into the field

* The Overseas Development Institute, Ltd , 1965. *The Decade of Development—a Study in Frustration?* (A lecture delivered in London under the auspices of the Overseas Development Institute on May 3, 1965.) By Barbara Ward. Pp. 23 (London. The Overseas Development Institute, Ltd., 1965.) 3*s* 6*d*.

of trade. In the developed world, the use of substitutes is constantly increasing because contemporary research concentrates largely on the products of the industrial countries. In the present world pattern of research, those adjustments which are necessary have continuously to be made by those countries which can least afford to do so, which have least economic choice and flexibility, and which are least able to adapt to rapid change.

Miss Ward thus underlines not only the comments of Prof. Blackett, but also the reasoned argument which Dr. S. Dedijer and others have advanced, for considered policy in regard to the use of science in the developing countries. Like Dr. Dedijer, moreover, she recognizes that there is a psychological difficulty, and that here again the colonial experience has not been helpful, if only because it has induced nationalist leaders to think that the economic basis of colonialism was sheer exploitation. There exists, in fact, a profound psychological disproportion between what Governments want, and what they are able quickly to achieve.

Beyond this, however, Miss Ward points out that progress has been made in selecting some of the strategic points for the most effective attack on these difficulties. She believes, for example, that we may be on the verge of a breakthrough in the field of population control. India and Pakistan are preparing to put a completely new emphasis on population policy in their next Plans; at the same time, the biological sciences are making striking advances in the understanding of the control of fertility. Taking these factors together, she suggests that within 20 years the lessening of the growth of population will not be the over-riding priority it is rightly felt to be to-day. We may, in the future, be giving far greater attention to the social aspects of population policy, namely, strengthening and enriching family life, enhancing the status and education of, and opportunities for, women and seeking to base relations between the sexes, not on licence but on friendship and respect.

She goes on to point out that far more attention is nowadays being directed to the essential inputs of mind, skill and experience required in policies of development. Education has surged forward, especially in Africa, to become the essential priority of modernization. Technical assistance to schools at every level has become the largest category of aid in manpower, while as a result of the Ashby Report, new strategies are being evolved in Nigeria to relate educational strategy to the proposed pattern of development. An effort is also being made to increase the number of people who are participating in this field of development planning: this is part of a wider realization that investment in brain-power may perhaps be even more important than investment in tools and should precede any massive increase in physical development.

One aspect of this deficiency of trained manpower is the shortage of people who can prepare projects for financing. More and more, assistance and skills must be developed to the preparation of projects, and although, in one sense, this is simply another aspect of the right administrative approach, it requires special skills. To this category of effective preparation and survey, creative foreign enterprise must be added, and here, unfortunately, the legacy of colonialism still disrupts a potentially creative field. Miss Ward questions whether the developed world sufficiently appreciates the difficulties experienced by local Governments when more than a certain proportion of their private industrial sector is foreign-owned. She suggests that in this essential field of investment far greater investigation of alternative methods of local participation is required. The idea of foreign enterprise as the spearhead, opening up new fields for ultimate local control, could be politically very attractive to many of the developing countries, while entailing no less to the investing companies; as a technique, it applies equally well to industrial as to agricultural enterprises.

There are also new perspectives in the field of trade, and she points out that the Trade and Development Conference of the United Nations sought to direct the attention of the developed world to the degree to which, by a whole sum of largely unconscious discriminations, it had so fixed world trade that most of its advantages tended to accrue to the rich rather than to the poor. A new range of proposals are now before us for dealing with these disproportions, all of which belong to a new realization of the degree to which patterns of world trade must be altered by specific political decisions. A new focus is also needed, and already a modest scheme is being prepared by the International Monetary Fund which gives primary producers virtually automatic access to the first part of their quotas from the International Monetary Fund. To encourage the provision of working capital for world trade, Miss Ward strongly supports the further proposals that the Fund should be empowered to offer certificates equal to 5 per cent increase in world trade. These certificates could be lodged with the World Bank as part of its near-liquid resources, but the International Development Authority would issue an equivalent amount of credit for long-term development loans to the poorer countries. This scheme for compensatory finance and world liquidity seems to her to cover more of the difficulties than any other strategy at present available.

Still more important, if more general, is her emphasis on the importance of an imaginative approach, rooted in neighbourliness and goodwill, to this whole question of overseas aid and development. Ultimately, in the pattern of world development, in the disproportion between the wealthy economies and the poverty of the rest of the world, policy will be decided, neither by the techniques nor the difficulties which have been described, but by an act of acceptance and an act of will. Aid as a policy will be safe when it is seen as the normal attribute of a developed society in this age of affluence.

Finally, Miss Ward suggests that, in spite of present economic difficulties, a special responsibility rests with Britain, for Britain is one of the leading industrial members in one of the few world-wide associations which includes rich and poor nations, Coloured and White, ex-imperial and ex-colonial, north and south. Membership of the Commonwealth offers a training ground, a field of experience as well as of need and contact, and of problems which present an unrivalled opportunity. Miss Ward suggests that the greatest aspiration for the British Commonwealth in the future might be to become a forcing-house, an experimental field, a partnership in the work of development which could set the pace in remaking the face of the Earth. That there is realism as well as optimism here can be seen even in the shadows of the Rhodesian situation in the attitude which Britain has so far adopted in continuing aid to those countries besides Rhodesia which have severed diplomatic relations. Miss Ward's address places the whole question of overseas aid in its proper perspective in overseas policy. In so doing it challenges further constructive thinking in those vital fields of technology and education where the scientist has so much to offer.

WILLIAM HARVEY

William Harvey
The Man, The Physician, and The Scientist. By Kenneth D. Keele. (British Men of Science.) Pp. xi+244+18 plates. (London: Thomas Nelson and Sons, Ltd., 1965.) 42*s*. net.

WILLIAM HARVEY: The Man, The Physician, and The Scientist is one of the "British Men of Science" series and is in no sense a biography, although it contains some biographical details. It is divided into three parts: Harvey the man, Harvey the physician, and Harvey the scientist. The first part contains such biographical details as are needed in this study. Harvey's career as a physician is presented fully and in an interesting way.

The main bulk of the book is devoted to Harvey the scientist and easily transcends in both interest and excellence the other two parts. *De Motu Cordis* is discussed and presented in many aspects, including the previous ideas of the functions of the heart and blood. Harvey's great book is presented and analysed in a way that makes the relevant chapters almost a companion to the work. Especially valuable is the chapter on Harvey's scientific methods, a theme which is continued throughout several chapters and becomes of great interest. Another chapter deals with the reception of Harvey's theory of the circulation of the blood; a discussion of particular interest when we can study the campaign with hindsight.

After *De Motu Cordis* the author deals thoroughly with *De Generatione Animalium* and again hindsight makes survey of the problems much easier. Especially interesting is Harvey's conclusion that fertilization of the ovum is due to some process he calls a "contagion, much the same way as medical men observe contagious diseases such as leprosy, lues venerea, plague, phthisis, creep through the ranks of men, and by mere extrinsic contact excite diseases similar to themselves".

This theme, that inevitably leads to and is explained by the spermatozoon and by bacteria, had to await the revelations of the microscope.

The author concludes inevitably that *De Generatione* compares unfavourably with *De Motu Cordis*. The essence of the contrast lies in the experimental basis of the one as opposed to the philosophical basis of the other. This is developed in a fascinating chapter on Harvey's scientific lineage, on his place in the history of discovery.

The neglect of the clinical application of Harvey's discovery is well presented and its gradual recovery through the work of Stephen Hales and the progress from Priestley's work to Lavoisier's recognition and description of oxygen and his finding of carbon dioxide in the expired air. The elucidation of the function of the pulmonary circulation thus opens the way for the clinical understanding of the whole circulation. The introduction of the Fick principle carries us further forward until Forssman's and Cournand's work on cardiac catheterization brings us near to the time when "we are at last reaping the fruits of this discovery in terms of the diagnosis of cardiac disease and treatment of the patient".

Dr. Keele concludes his invaluable book with a significant paragraph: "The true essence of greatness lies in the conquest of time. And as we now leave Harvey we can see this little sallow-faced man with the bright eyes standing like a colossus astride the great space of 2,300 years, with one foot in the ancient Greek library of Aristotle, and the other in the operating theatre of the modern cardiac surgeon".

This is an excellent book which I strongly recommend. It should be read by all those interested in the circulation, either physiological or clinical; it is much more than an essay in the history of medicine. BROCK

CONSERVATION: WHAT IS IT?

Readings in Resource Management and Conservation
Edited with Introductions by Ian Burton and Robert W. Kates, with the assistance of Lydia Burton. Pp. xi+609. (Chicago and London: University of Chicago Press, 1965.) 8.50 dollars; 63*s*.

WHEN will someone write a text-book on conservation and resource management that draws its examples and conclusions from British situations and experience and is written in simple and straightforward English? The question is prompted by two unconnected statements in the admirably succinct preface to *Readings in Resource Management and Conservation*, in which the editors explain their aim. It is "to acquaint students in courses in conservation and resource management with some of the wide variety of material to be found outside the standard texts" available in the United States and Canada. In Britain, where broadly based courses in conservation and resource management are a novelty to be counted on the fingers of one hand, there is not a single wide-ranging text-book available that has been written with the British student in mind. That such a book is required is undoubted; if one may quote from Burton and Kates (out of context) it should seek to provide "an adequate conceptual framework for resource management and conservation"—a field that is "wide, varied and amorphous". Existing (American) texts have not been notably successful in this particular endeavour, either in content or expression.

Readings in Resource Management and Conservation is an anthology of writings on conservation and the "social and behavioural science" aspects of resource management. It incorporates a wide range of selections of historical interest—including polemical statements of the type so difficult to present in traditional text-books—and papers on topics at present of concern in the United States, as well as some not readily accessible or fugitive material. All this has been arranged, and to some extent selected, in such a way as to resemble a monograph more than a text, short bridge-passages providing a linking introduction to each new chapter. This treatment is extremely effective and the editors have undoubtedly, as they express it, "taken a step towards a conceptualization of a field which lacks structure and form as it also lacks theory". (Incidentally, it was this sentence that inspired the second half of the question with which this review opened. Far too much jargon and unnecessary word-coining are blotting the literature of ecology and conservation; it is time for a cleansing and a return to simple and readily understandable English.)

A short, four-page introduction to the anthology traces the pattern of its contents: in the papers selected, "man is seen variously as a biological population, an exploiter, a conserver and a manager of resources; as an economic optimizer, a nature lover and in many other guises". Nature also is variously regarded: "now as an impersonal force that moulds the destinies of man, now as a complex web of life arranged in a delicate balance that we disturb at our peril, now as a malleable set of resources that may be used at will". The selections present a diversity of views ranging from the determinist extreme—"Malthusian in its concern with the adequacy of resources and conservationist in its prescription for policy"—to the attitude towards Nature that is "optimistic in its view of technological advance and the sufficiency of resources" and concerns itself mainly with the technical and managerial problems of development.

Part 1 of the book, "The Malthusian Equation", considers the problem of population growth and the finite earth; Part 2 is concerned with "The Conservation of Limited Resources"; Part 3 with "The Management of an Expanding Resource Base". Particularly revealing of much loose thinking are the selections in Part 2 which deal with the growth of the conservation movement and

the conservation ethic. After reading them, every reader will feel constrained to seek to define for himself (since no one else has yet done so satisfactorily) just what conservation is, what it means, and whether it is a way of life, a state of mind or a field of knowledge, or some or all of these things, or none.

Readings in management occupy more than half the book and cover a wide range of subject, type of resource, regional setting, objective and research technique. They are grouped into chapters dealing with the managerial experience, resources and economic development, scientific and technological change, and the choice of alternatives. Among the selections offered (and to quote only about a third of the titles) are accounts of the Columbia Basin and Tennessee Valley Authority projects; the management of the Harvard Forest; the conflict between fish and power resources in the Pacific Northwest; soil erosion control; conservation and stock reduction on a tribal range; wilderness perception and use; natural resources and economic development; the diffusion of agricultural innovations; and a safe minimum standard as an objective of conservation policy. Taken together, the papers "suggest a picture of managerial activity marked by less success than is normally assumed", and a "failure to anticipate change or to accommodate differences in value", both of which are intractable managerial problems.

This is a happily conceived, efficiently contrived and unusually stimulating book; every chapter of it arouses thought. It is well produced, tastefully laid out, a pleasure to handle and good value for money. It should be compulsory reading for resource managers and conservationists, however defined. W. J. Eggeling

JURASSIC STRATIGRAPHY

Jura

By H. Holder. (Band IV of the Handbuch der stratigraphischen Geologie.) Pp. xii + 603. (Ferdinand Enke Verlag, Stuttgart, 1964.) DM 129.

THE appearance of a new book on world Jurassic stratigraphy is bound to provoke comparisons with the well-known synthesis of W. J. Arkell published ten years ago, almost exactly a century after the publication of *Der Jura*, by F. A. Quenstedt, the first major treatise on the Jurassic. *Jura*, dedicated appropriately to the memory of these two eminent scholars, differs in important respects from its immediate predecessor, to which, indeed, it forms an admirable complement.

While a three-page 'retrospect' at the end of Prof. Hölder's book is no substitute for the five general chapters in *Jurassic Geology of the World*, which make stimulating reading for all types of geologist, there are a number of compensating advantages. In the first place there is a much fuller emphasis on the classical areas of Europe, especially central Europe. An abundance of illuminating text-figures replaces the admittedly often beautiful but less useful photographs in Arkell's work. Taking into account also the flood of new literature in the past decade, which receives due attention, these features suggest that Holder's book may actually prove more valuable as a reference work for the practising Jurassic stratigrapher.

The book is divided into two sections, with emphasis respectively on chronology and regional geology. Some compromise is involved here. Thus the type sections of the English Middle and Upper Jurassic are considered better dealt with in the chronological section, whereas the English Lias and south German Malm, where type sections are not considered necessary, are treated in the regional section. Such an approach is rather inconvenient for the reader, who is obliged to consult both sections to learn all he can about a given part of the Jurassic in a classical European area.

After a critical review of the evolution of the zonal concept, the development of successive Jurassic stages in the type areas and neighbouring regions is fully considered; the section ends with a palaeontological appendix devoted to a discussion of several interesting fossil groups.

Difficulties concerning the definition of the top of the Jurassic are not hedged, and Casey's correlation of the Jurassic–Cretaceous boundary in the boreal realm with the Tithonian–Berriasian boundary in the Mediterranean is viewed with scepticism. The regional section includes a concise but fair review of recent work on the British Jurassic, though the author adheres to the outdated concept of posthumous axes of uplift.

In contrast to the ample treatment of the European Jurassic, the rest of the world is dealt with somewhat cursorily and the information is not always up to date. Thus the Franciscan Group of California is now known to range in age from Tithonian to Cenomanian, and is considered to be a eugeosynclinal equivalent of the Knoxville. The Nevadan orogeny is likewise known to straddle the Jurassic–Cretaceous boundary, and no major foundered Pacific landmass need be invoked to account for the origin of the Franciscan sediments.

The cost of Prof. Hölder's fine and well-produced book is unfortunately high, but it deserves a place on the shelves of geological libraries throughout the country. One is provoked to the reflexion that, with its traditional emphasis on stratigraphic correlation by means of ammonites, it may prove to be the last comprehensive Jurassic treatise of its kind. While important correlation problems remain, notably in the Upper Jurassic, interest has begun to shift towards a much fuller understanding of the rocks and of the fossils as representatives of past life. It is indeed astonishing how few detailed sedimentological and palaeoecological investigations have been undertaken in a geological system that has received intensive scrutiny for more than a century. A. Hallam

ATMOSPHERIC AND SPACE ELECTRICITY

Problems of Atmospheric and Space Electricity

(Proceedings of the Third International Conference on Atmospheric and Space Electricity, Montreux, Switzerland, May 5–10, 1963.) Edited by Samuel C. Coroniti. Pp. xiv + 616. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 200*s*.

PROBLEMS of Atmospheric and Space Electricity is a valuable document, well edited and handsomely produced. The proceedings and extensive discussions will certainly be regarded as historic; within a very few years space-probes and directed satellites will have produced information on the atmospheres of other planets to compare and contrast with that of our own.

Though the workers represented at Montreux and their predecessors have had great successes, including the discovery and elucidation of the cosmic rays, knowledge of the electrical state of our own atmosphere is still far from complete. We have, as yet, a very limited amount of information about its outer edges, the ionosphere and the exosphere. It was, therefore, with some sense of urgency that this gathering of 160 workers in terrestrial atmospheric electricity met to survey their subject before it becomes translated to other worlds. Cosmic rays have already left their purview, the maintenance of the general ionization of the lower atmosphere has been largely reduced to order, though bedevilled by the fouling from atomic-bomb fallout. Two outstanding problems occupied most of their attention: the mechanism of thunderstorms and the electrical state of the ionosphere.

Thunderstorms offered the opportunity for a full-scale debate, almost a battle, between rival experimenters and theorists. On the one side were Latham and Mason with their well-authenticated evidence that thunderstorm charges arise from the impact of supercooled droplets of water on larger particles of soft hail, effectively at a

lower temperature, the former giving rise to minute, positively charged splinters to be blown upwards relative to the larger rime-covered and negatively-charged hail.

On the other were Workman and his colleagues from New Mexico, equally convinced that the charging arises from multitudinous contacts between hailstones and already frozen drops of water. Argument was quickly switched, therefore, to such evidence as there is about the scale of the two different activities and about the milieu in which they occur. The key question which soon emerged was to what extent the thundercloud can accumulate charge of one polarity in one region and of the opposite polarity in another. As Dr. Ross Gunn was to emphasize, full understanding can come only when we have reliable determinations of the nature and the concentrations of the various charge carriers as well as their velocities. Existing evidence is little more than speculation and the difficult task of distinguishing between the two schools (not to mention a third claimant, Dr. Vonnegut, who has propounded a purely convective theory of the thunderstorm) now lies with the meteorologists. At the present time, in the words of *Exodus* IX, verse 24, we are left with "hail, and fire mingled with the hail, very grievous".

On the second major question an important paper was presented by E. C. Whipple, jun., on the electrification between the troposphere and the bottom of the *D* layer of the ionosphere, a region inaccessible to balloons and difficult to explore from rockets, which disturb the local environment. This is, however, considered the outstanding task for space-vehicles. The day is not far distant when the problems of the dusty atmosphere of Venus and the gigantic atmosphere of Jupiter with its turbulent red spot will present new targets for our ingenuity. In the meantime we have, as an urgent task, to study intensively the language of the radio-emissions from both of them with earth-bound equipment.

A peaceful battle was followed by a feast of informative papers. Many will be stimulated by them. All are worth reading.

BASIL SCHONLAND

ABERRATIONS OR REVELATIONS?

Drugs of Hallucination

The Uses and Misuses of Lysergic Acid Diethylamide. By Sidney Cohen. Pp. xviii + 268. (London: Secker and Warburg, 1965.) 30*s*. net.

DR. COHEN, who is a psychiatrist, has written a good, popular account of the hallucinogens, especially lysergic acid diethylamide (LSD), at a cost of less than a penny a page. *Drugs of Hallucination* is open-minded but not detailed, fair but not neutral. The dangers of therapy with LSD, to therapist as well as patient, are emphasized no less than the enlightenment of "instant Zen". The book describes admirably the terrors as well as the joys of LSD-taking, with the aid of lengthy extracts from subjective accounts. These were, of course, made after the experience had ended: at the time, the subject is relatively (sometimes absolutely) mute, either catatonic or entranced with his jewel-studded umbilicus. It is worth pointing out once again that even those who have enjoyed the experience are invariably dissatisfied with their subsequent attempts to put it on paper. Whatever Mr. Wilson and Mr. Trocchi say, drugs do not help the user to express himself. They cannot help those who have never written to write at all, and those who are at best indifferent writers continue to write indifferently.

The volume contains an elementary account of hallucinogen chemistry in one appendix, and the sketchiest of phenomenological comparisons of sensory deprivation, psychotic experiences and experiences of LSD in another. There is also an index. What there is not—and this is really unforgivable in a book on a serious subject, even if it is intended for a lay audience—is adequate documentation of statements. There are fourteen titles in the bibliography, which are perhaps enough, for the literature on this subject is not of such outstanding quality that it needs to be quoted extensively. Even so, they are not altogether the best titles, nor relevant at all in some cases: and, what is most serious, they contain no mention of his own experimental work; and Dr. Cohen draws on this continually in the body of his book. Since he nowhere in the book describes what he did, to how many, when and with how much (all important matters to the psychopharmacologist), the omission is, to say the least, a nuisance.

Dr. Cohen is a respected and careful scientist, however, whose professional papers can easily be found by reference to the proper sources. This cannot be said for many so-called 'workers' in the field of the hallucinogens, reports of whose activities are all too frequently found in sensational rather than scientific literature. It is an ethical condition of work that the scientist should make his results available in a form that allows any other scientist to attempt to reproduce them, as a preliminary step to building on them. This condition is too seldom met in a field of research that may be as important to the future of mankind as the wheel or nuclear fission. Any tool that may possibly help unravel the torments of our existence is worth close, critical and documented examination.

Most of us are inclined to regard the intellect as the most interesting characteristic of man: but his future development may well depend on deeper understanding and use of his emotions, and research of the best kind into the hallucinogens may be invaluable here. It may be that the effects of LSD are so variable, even in the same individual, because its substrate is the minute-to-minute emotional state of the subject. Such drugs as alcohol or amphetamine are also variable in their effects but these are relatively predictable, perhaps because they depend on mood. If LSD itself works below the level of the intellect, it is all the more important that those who investigate it should not do so as well. As Dr. Cohen points out in his simple but good book, a disturbingly high proportion of those who administer LSD to others go mad themselves!

C. R. B. JOYCE

USE AND MISUSE OF LSD 25

Utopiates

The Use and Users of LSD 25. By Dr. Richard Blum and associates. Pp. xv + 303. (London: Tavistock Publications, Ltd., 1965.) 58*s*. net.

LYSERGIC acid diethylamide (LSD) has been widely used as a research tool in neuropsychopharmacology, and as an adjunct to psychotherapy. It is also, unfortunately, being misused, particularly in the United States, as a drug purveying what has succinctly been called 'instant Zen'. *Utopiates: The Use and Users of LSD 25* is a sociological survey of this phenomenon to try to determine who uses the drug in this manner and why. Naturally, the material was not easy to obtain, but Dr. Blum and his co-workers managed to contact ninety-two persons who had taken LSD. These they divided into four groups: (1) an informal professional group, mainly psychiatrists, who had taken the drug outside any recognized research project; (2) a therapy patient sample who had been given LSD by a psychiatrist as part of treatment; (3) an informal black-market sample; (4) the religious-medical centre group associated with an organization (IFIF*)–using the LSD experience for a defined religious purpose. These were analysed with respect to a very large number of factors, including type of person involved, their motives, types of reaction obtained, repeated use, proselytizing activity, community attitudes, group interactions, etc. This provides a mine of interesting data on the present-day American scene. The over-all theme appears in the form of earnest attempts by followers of Aldous Huxley to use

* International Federation for Internal Freedom.

LSD for social, personal and religious purposes, and the no less earnest opposition by others who believe this to be dangerous, misguided or wicked. Dr. Blum's survey is factual and liberal in attitude. It turns up some facts of general psychiatric interest. For example, he reports that six out of a known population of 300 LSD users had psychotic reactions of such severity to necessitate hospital admission "for short or long periods". It was felt to be impossible to predict who would get an LSD psychosis on the basis of previous personality aberration. The second fact is that one-third of subjects who had taken LSD as volunteers in a recognized research project went on to take it again on their own, in some cases regularly.

A brief but admirable chapter by Keith Killam follows on the psychopharmacological aspects of LSD, particularly its dangers. This is followed by reports on the "Mexican Psychedelic Training Centre", established by Leary and Alpert. The first is by a psychiatrist outside the group—J. J. Downing. This is again tolerant and yet does not gloss over the difficulties involved, which finally led to the expulsion of the group from Mexico. The second is by Leary and Alpert themselves and gives their own point of view.

Joel Fort, a specialist in the treatment of alcoholism, puts LSD in its proper perspective against the grisly facts of the misuse of alcohol, barbiturates, amphetamine, etc., in our culture.

A particularly fascinating chapter is a survey by Blum of police attitudes towards drug uses. A sample of 27 police officers was asked to rate people of different categories as to their degree of menace to the community. Members of the United States Communist Party came out on top (score 27), followed by heroin addicts (26); LSD users (20) came middle in the list below the Mafia and Black Muslims (23), but above members of the John Birch Society (16).

The essays conclude with a forthright statement by Edward Comber, director of the Bureau of Criminal Information of the San Francisco Police Department, that LSD use, outside medical and research projects, is both dangerous for the individual and society and morally wrong.

J. R. Smythies

MASTERS OF MICROBIOLOGY

Three Centuries of Microbiology

By H. A. Lechevalier and M. Solotorovsky. Pp. 536. (New York, London and Sydney: McGraw-Hill Book Company, 1965.) 12.50 dollars; 100*s*.

Three Centuries of Microbiology opens with a preface which contains the following explanatory statement: "Since we feel that nobody can explain a discovery as well as the person who made it, our text contains numerous, often extensive, quotations from classical papers that outweigh the volume of our own writing. Since many of the papers that we are quoting were not written in English, our work has often been that of translators." This adds considerably to the value of the book.

The book is essentially a collection of biographies of outstanding microbiologists and of other scientists whose work has influenced them. It is divided into 12 chapters. Each chapter has its own useful list of references, usually to biographies of the scientists concerned, and the book closes with a good working index.

The first chapter is a historical survey, starting with Girolamo Fracastoro (1483–1553), whom the authors describe as "the father of the germ theory of disease". It briefly describes the general scientific background to the development of the microscope and the gradual development of microbiology up to the time of Pasteur, a period of more than 300 years, illustrating this with some twenty 'microbiographies'. One chapter each, of about fifty pages, is devoted to the lives and work of Pasteur and Koch. Most of the information is readily available in other published biographies, but it is interesting to note that the origin of the key word 'microbe' is given by Pasteur in a joint paper with Joubert and Chamberland (*C.R. Acad. Sci., Paris*, 86, 1037; 1878) as a "new and fortunate expression proposed by M. Sédillot" (*ibid.*, 86, 634; 1878).

A lengthy chapter entitled "Bacteria as Agents of Disease" deals with work in both Europe and America on tuberculosis, diphtheria, bubonic plague, tetanus, dysentery and bacterial plant diseases. The workers mentioned include Villemin, whose "Studies on Tuberculosis" (1868) proved an inspiration to Koch and who furnished conclusive proof that tuberculosis was contagious, Loffler, Gram, whose method of differential staining of bacteria made an important contribution to bacteriology, Roux, Yersin, Kitasato, the pioneer Japanese bacteriologist, Shiga, T. J. Burrill, who was the first to indicate the role of bacteria as disease-producers in plants, and Erwin F. Smith, whom the authors describe as "the Koch of phytopathology".

The next two chapters discuss immunology, cellular and humoral. The first of these chapters is concerned chiefly with the lives of Metchnikoff and Almroth Wright and their work on phagocytes. The second traces the development of serology, work on anti-toxins for diphtheria and tetanus, BCG vaccine for tuberculosis and antigens, referring extensively to the work of Nuttall, Behring, Calmette, Guérin, Bordet, Richet and others. Under the heading "From Soil Microbiology to Comparative Biochemistry" the authors describe the work of Winogradsky and Beijerinck on nitrogen fixation in the soil by microorganisms, and the work of Kluyver on microbial biochemistry. The chapter headed "Viruses and Rickettsiae" traces the elucidation of the nature and properties of these micro-organisms and deals in detail with the work on the diseases caused by them and with the introduction of the electron microscope which proved such an important tool in the study of viruses and in the whole field of microbiology. A chapter on mycology gives an account of the origin of interest in fungi and describes the development of fungicides and of medical mycology. A chapter on protozoology describes the early work on the nature and classification of protozoa by Hooke, Leeuwenhoek and others which led to the realization of the responsibility of pathogenic protozoa for diseases such as malaria, and ends with good accounts of such workers as Theobald Smith, Bruce, Laveran, Manson and Ross. Under the title "Chemotherapy" the authors trace the three major paths in its development: the use of natural products such as quinine, the search for synthetic agents resulting in salvarsan and prontosil, and the investigation of the metabolic products of micro-organisms which led to the discovery and development of the antibiotics penicillin, streptomycin, chloramphenicol, the tetracyclines and the semi-synthetic penicillins. In connexion with penicillin, I wish to correct a statement, which appears on page 468 of this book and in almost all the numerous books on this important mould metabolite, to the effect that the work carried out in my laboratory at the London School of Hygiene and Tropical Medicine was brought to a premature close after the publication of the paper by Clutterbuck, Lovell and Raistrick (*Biochem. J.*, 26, 1907; 1932) because of the death of Clutterbuck in 1932 and Lovell's departure to the Royal Veterinary College in 1933. In fact, Dr. P. W. Clutterbuck died at the end of 1937, having, in the interval since 1932, published a number of valuable papers.

The final chapter on genetics starts with Mendel, described as "the founder of genetics", born in 1822, and de Vries, who, working with plants, introduced the concept of mutation, and goes on to describe the work of microbial geneticists including Beadle, Tatum, Avery, Lederberg and Pontecorvo.

The authors conclude the book with an epilogue in which they say: "More than a hundred years have passed

since Pasteur started to investigate the secrets of the simplest forms of life, which have turned out to be so complex". They are to be warmly congratulated on having produced such a readable history of this fascinating subject. I recommend the book to all microbiologists and other scientists of catholic tastes.

HAROLD RAISTRICK

ALL THE MAMMALS

The Mammals

A Guide to the Living Species. By Desmond Morris. Pp. 448 (300 photographs). (London: Hodder and Stoughton, Ltd., 1965. Published in association with The Zoological Society of London and Granada TV Network.) 63*s*. net.

THE Mammals: A Guide to the Living Species deals with the orders of mammals in turn. We are given a classified list of the living species of each order, followed by photographs and brief descriptions of a selection of the species. The lists will presumably be used mainly by zoologists and it is rather surprising to find them in a book which is otherwise designed for a much wider public.

The lists have been compiled mainly from a dozen fauna lists which between them cover the world. They give the systematic position, scientific name and English name (if any) of each species, with an indication of distribution and a reference to a taxonomic work where fuller details may be found. The authors of species, and synonyms, are omitted. The lists of bats and rodents have been kept reasonably short by giving the number of species, and not their names, whenever a genus includes several species. Twice as much space would have been required to list the mammals if this had not been done. The lists of the other orders include all the specific names. Dr. Morris estimates that a complete list of the species of living mammals, with synonyms and authorities, would occupy at least 2,000 pages. We may regret that he has not been able to give us such a list, but he has provided a very useful list in the 80 or so pages that he (or his publisher) has felt able to spare for the purpose. There does not appear to be any other modern list of the mammals of the world.

There are, it appears, 4,237 known species of mammals. 300 of them have been selected for illustration and brief description. These include a much higher proportion of the primates, carnivores and ungulates than of the insectivores, bats and rodents. This is inevitable, because the latter group of orders is so large and because the former one is so well represented in zoos. Dr. Morris is curator of mammals to the Zoological Society of London, and most of his readers must depend largely on zoos for their experience of non-domestic mammals. Nevertheless, I would gladly have given up a few of the duller monkeys in return for some more zalambdodont insectivores.

The descriptions deal with the more remarkable features of the habits and anatomy of each species. The selection of material for them has been excellent, though it was, perhaps, a mistake to give every species the same amount of space. In some cases, when other very similar species have been described, the requisite 250 or so words seem to have been hard to find. In other cases, they are not nearly enough. In the account of the European rabbit, for example, burrows and refection are discussed, but there is too little space to cover the equally interesting topics of myxomatosis and the reabsorption of embryos. A few opportunities have been missed; there is, for example, no mention of the difference in echo-location mechanism between rhinolophid and vespertilionid bats, which could be illustrated very well by photographs. No authorities are cited for the information given in the descriptions.

Most of the photographs are of captive animals. A red deer does not look its best against a background of bars, wire netting and a perambulator. A few of the photographs are poor, but most illustrate their subjects adequately.

The introduction includes a very worthwhile attempt to explain the success of the mammals in popular terms. Fuller explanations of some points would have been welcome, and it seems unfair to write about the mammals "eliminating the inefficient mixing of venous and arterial blood" since recent experiments indicate that very little mixing occurs in reptile hearts[1,2].

This is a useful book, and an attractive one.

PLANT ANATOMY

Plant Anatomy

By Prof. Katherine Esau. Second edition. Pp. xx + 767 (96 plates). (New York and London: John Wiley and Sons, Inc., 1965.) 105*s*.

ALTHOUGH plant anatomy can no longer claim so great a share of a well-balanced botany course as in former years, it is equally certain that no botanist should be without a sound knowledge of plant form and structure. The corresponding need for a good modern text-book of plant anatomy has now been met by this second edition of Prof. Esau's *Plant Anatomy*.

The previous edition of this book, published in 1953, received much praise from many users, and all the good things said about the first edition apply equally to the present one. The clearly written text is illustrated by many text-figures and by a large number of photographs, which have been increased to 96 plates in this edition, as compared with 85 in the first edition. There have been few changes in the general plan of the book, and with one exception, Chapter 13, with the new title "Secretory Structures", as opposed to the previously more restricted topic of "Laticifers", the chapter heads remain the same. A great deal of new information has been incorporated in the text, but appropriate condensations and omissions have enabled this integration to be made without an undue increase in length, now 767 pages instead of 735.

The principal changes have naturally been in the sections where recent research has been active, notably in the chapters dealing with "The Protoplast" and "The Cell Wall", which now include condensed, but informative, accounts of modern ultra-structural research. The chapters on "Meristems and Differentiation" and "Apical Meristems" have been extended to cover new developments, such as the culture of isolated cells and experimental studies by various workers on plant morphogenesis.

But this new edition, like the previous one, is primarily concerned with the broad treatment of fundamental aspects of plant anatomy. As a consequence of this approach it is inevitable that individual readers may be disappointed with the curtailed accounts of certain special topics. Thus, there is little consideration of the interesting differences in the detailed structure of secondary xylem which permit the identification of commercially valuable timbers. There is also only brief mention of the varied anatomical modifications characteristic of plants with different ecological requirements. On the credit side, the omission of details of this kind has permitted the inclusion of chapters dealing with "The Flower", "The Fruit" and "The Seed".

In sum, this book is of value both as a reference work for any student of botany, and even for general reading by those interested in acquiring a good grounding in plant anatomy. It is above all a scholarly treatment in which the author has carefully selected the more significant items from the great mass of detailed information available. The book is well produced and the two drawings of transverse sections of collenchyma make an attractive and appropriate dust-cover.

A. ALLSOPP

NEW BIOCHEMISTRY BUILDING, IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, LONDON

THE new biochemistry building, which is under the direction of Prof. E. B. Chain, was formally opened on November 4, 1965, by H.M. Queen Elizabeth the Queen Mother, chancellor of the University of London, at a ceremony presided over by Lord Sherfield, chairman of the Governors of the Imperial College of Science and Technology, in the presence of Sir Patrick Linstead, rector of the College, Sir Thomas Creed, vice-chancellor of the University, and its principal, Sir Douglas Logan.

The construction of such a large and well-equipped university biochemistry department is an exceptional event and marks the importance which the Imperial College of Science and Technology attaches to this rapidly expanding discipline.

While this represents a new phase of the College's interest in biochemistry, it is now more than 50 years since the subject first received official recognition. Thus, in 1913 a small Sub-department of Biochemistry was set up in the Department of Botany under the direction of S. B. Schryver, who was appointed full professor in 1920. On his death in 1929 he was succeeded by a former pupil, A. C. Chibnall, who was subsequently made full professor in 1936. Prof. Chibnall resigned from the College in 1943 to take up the Sir William Dunn chair of biochemistry at Cambridge, after which the chair at Imperial College remained vacant, although some research was continued under the direction of Dr. H. W. Buston.

With the rapid post-war progress in biochemistry, it was felt, in the mid-1950's, that the College should modernize and considerably expand the existing facilities for biochemical research to a level commensurate with that of the other well-established scientific and engineering departments. As a first step it was, therefore, necessary to re-establish the chair of biochemistry. In the course of a visit to Rome, Prof. P. M. S. Blackett saw Prof. E. B. Chain, who was responsible for the creation of the internationally recognized Biochemistry Department of the Istituto Superiore di Sanità. His Department was comprehensively equipped for metabolic studies and included an extensive fermentation pilot plant, and the possibility of setting up a similarly equipped department at Imperial College was discussed. Following a visit to Rome by the rector, Sir Patrick Linstead, a tentative project was prepared. Unfortunately, analysis of the estimates for constructing a department of the desired dimensions showed the cost to exceed the funds then available and the scheme was temporarily shelved.

In 1959, Prof. Chain discussed the financial difficulties of the project with the late Lord Nathan, who was the first chairman of the recently founded Wolfson Foundation. Lord Nathan suggested that the College should apply for support to the Trustees of the Foundation who, following numerous prolonged discussions, agreed, subject to the appointment of Prof. Chain to the chair, to contribute £350,000 towards establishing the new department. This would include the building and equipping of modern laboratories for biochemistry and microbiology to be known as the Wolfson Laboratories.

The original plan was to build the Wolfson Laboratories, including the fermentation pilot plant, at the rear of the Royal College of Science block and to meet the remainder of the Biochemistry Department's space requirements by adapting part of the existing building. Following the subsequent approval by the University Grants Committee, however, of a scheme to redevelop the present site of the Royal College of Science, these plans were changed and it was decided to house biochemistry in a completely new building, which was seen as the first stage of this redevelopment.

Prof. Chain was appointed to the vacant chair of biochemistry and took up his appointment on October 1, 1961. Demolition of the old building began early in 1962, and the new laboratories, having a total floor space of 63,000 ft.^{2} (not including the pilot plant), were completed in the summer of 1965 at an approximate cost of £1·2 million. The architects were Architects' Co-partnership and the main contractors Tersons Ltd.

The Department is designed and extremely well equipped for research covering a broad range of metabolic studies in animals and micro-organisms and to a lesser extent in plants. In addition to these more usual aspects of biochemical research, there is particular emphasis on the development of instrumentation such as the automation of analytical and fermentation processes.

The financing of the research is being greatly facilitated by three major sources of funds which are supplementary to the normal awards of the University Grants Committee. These are the Science Research Council, which is making a grant of £100,000 in support of research on fermentation biochemistry and technology and biosynthetic mechanisms in micro-organisms; the Trustees of the Fleming Memorial Fund for Medical Research, who have granted £50,000 over 5 years for basic medical research; and the Medical Research Council, which has established a Metabolic Reactions Research Unit under the honorary direction of Prof. Chain.

The research programme is primarily a direct extension of the various lines developed by Prof. Chain and his colleagues at the Istituto Superiore di Sanità during the past 15 years where, at the invitation of its director, Prof. Domenico Marotta, he had organized and directed the Biochemistry Department which included the International Centre for Chemical Microbiology.

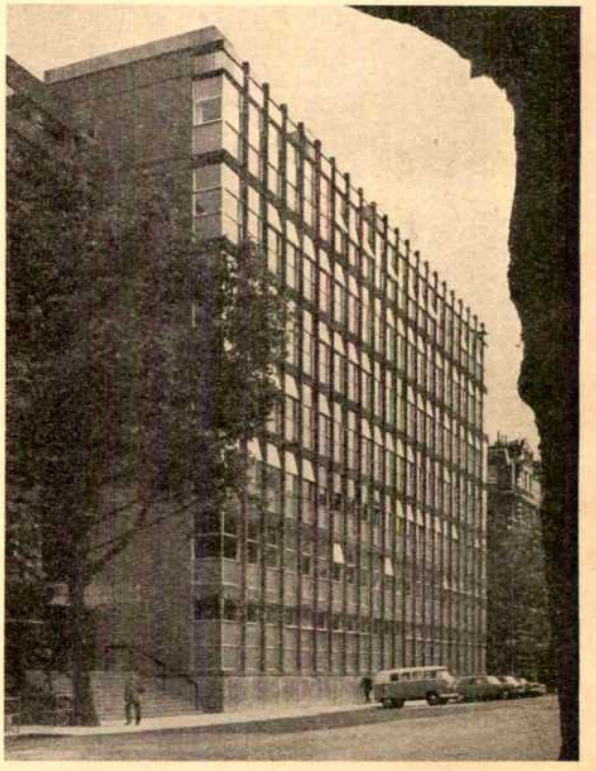

Fig. 1. Front view of the new biochemistry building, Imperial College of Science and Technology, London

The new Department contains 33 laboratories and three classrooms located on six levels, providing accommodation for about a hundred research workers and postgraduate students and the appropriate technical staff. An additional number of rooms, which are not occupied for prolonged periods and, therefore, do not require daylight, are located in the 'inner core' of the building; they are ventilated and house instruments, high-speed centrifuges, chromatography equipment, wash-ups, incubator rooms, store rooms and photographic equipment.

The basement contains a large mechanical workshop and air-conditioned and temperature-controlled animal houses. All the laboratories on the second level are devoted to research on animal biochemistry, the centre of interest being the study of hormonal regulatory mechanisms and of neurochemical problems. For the more physiological and pharmacological aspects of this research, special physiological laboratories are provided on the third level. The Metabolic Reactions Research Unit is housed in the biochemical and physiological laboratories on the second and third levels.

The laboratories on the fourth level are designated partly for research on problems of chemical microbiology and partly for isotope analysis by Geiger–Müller counting techniques, scintillation counting and mass spectrometry. A 'hot' laboratory for the preparation of ^{14}C- and tritium-labelled compounds is also available. The research problems under investigation include studies of biosynthetic pathways of microbial metabolites of biological or biochemical interest and the enzyme systems involved, the elucidation of the chemical structures of new compounds belonging to this category and some aspects of non-specific immunity.

In close conjunction with and in support of the biochemical studies, microbiological investigations are carried out in laboratories located on the sixth level. These are concerned with investigations of the morphology, physiology and genetics of the micro-organisms producing the metabolites under investigation, strain selection and improvement, some of the more botanical aspects of the interaction between fungi and plants and tissue culture.

For the development of new instrumentation required for the sections of animal biochemistry and chemical microbiology, as well as the fermentation pilot plant, a series of electronics laboratories is provided on the fifth level. The development of automatic scanning devices for the quantitative evaluation of bi-dimensional radiochromatograms and various kinds of column chromatography procedures, with the computerized evaluation of the results, is under active investigation; other problems under investigation include the automation of fermentation processes and analytical procedures. Adjoining the instrumentation section is a series of laboratories for the study of new methods of biochemical engineering, particularly in the fermentation field.

A special feature of the Department, and one that is unusual for a university biochemistry institute, is its fermentation pilot plant of semi-industrial dimensions for the bulk production of (non-pathogenic) micro-organisms and microbial metabolites of biochemical or biological interest, and the study of fermentation processes of industrial interest. It contains a series of stainless steel fermenters of 20, 50, 300 and 3,000 l. capacity which are run continuously 24 h a day on a shift basis, and is provided with all the filtration and extraction equipment required for working up the largest quantities of micro-organisms and culture media obtainable in the fermenters. Attached to the pilot plant is a series of microbiological laboratories for the preparation of the inocula and for routine microbiological and chemical tests. The pilot plant serves the needs of the chemical microbiology section of the Department in the first instance, but it is hoped that it will eventually be possible to meet at least some of the requirements for microbiological material frequently occurring in outside university and other biochemical research laboratories.

No undergraduate studies are planned, but a 2-year postgraduate course in general biochemistry, chemical microbiology and fermentation techniques leading to the award of Diplomas of Membership of the Imperial College of Science and Technology (D.I.C.) and M.Sc. degrees was initiated at the start of the present session. Teaching laboratories to accommodate forty postgraduate students and a seminar room are located on the third and fifth levels.

The underlying unification of the apparent diversity of research activities is seen as a consequence of the universal nature of most fundamental biochemical processes, in the detailed investigation of which it is obviously desirable to minimize any limitations on the choice of the most suitable experimental biological system. This thesis was strongly argued by Prof. Chain in his inaugural lecture, which he entitled "Landmarks and Perspectives in Biochemical Research".

In this lecture he outlined the major historical landmarks in biochemical research and detailed his own approach to the subject, while in his closing remarks he directed attention to what he considered to be important prerequisites of successful research. With regard to the immensity of United States contributions to biochemistry, it was emphasized that, although in Britain there must of necessity be a proportionately smaller number of research institutes, there is no reason why the individual units should not be at least as well equipped as their United States counterparts, and furthermore that there is much to be gained by close contacts with our colleagues in the United States involving regular visits by both senior and junior research workers. However, in addition to overcoming the frustration inherent in inadequate financial support for research, he emphasized a less frequently stated but equally important problem, namely, the lack of senior positions for young, promising biochemists who are consequently prone to lend sympathetic ears to the overtures of overseas laboratories.

In order to nurture the spirit and energy which are the birthright of any new department, it is vital to recognize and take all possible steps to avoid those frustrations which alone can prejudice the enthusiasm, dedication and congenial research atmosphere so essential to the successful study of the secrets of nature. ROBERT THOMAS

EVAPORATION OF LAVA AND ITS CONDENSATION FROM THE VAPOUR PHASE IN TERRESTRIAL AND LUNAR VOLCANISM

By DR. BERNARD VONNEGUT, ROBERT K. McCONNELL, jun., and RONALD V. ALLEN
Arthur D. Little, Inc., Cambridge, Massachusetts

STILL and motion pictures of eruptions on the volcanic island of Surtsey, taken in February 1964, show an interesting phenomenon associated with the fountains of molten lava. When the fountains are active, a dense cloud of dark smoke forms, which is carried off by the wind (Fig. 1). More recent observations of this volcano reported by Björnsson[1] in the summer of 1964 describe a similar phenomenon in which a cloud of dark smoke was observed to form down-wind of the quiet lake of molten lava that filled the crater.

These dark clouds, except for their colour, are quite similar in location and appearance to the clouds of white steam from erupting geysers and from heated pools in geothermal areas. The resemblance between the steam clouds and the volcanic clouds is so pronounced that in our opinion there is little doubt that they are formed by a similar mechanism. It appears that the hot lava has a high enough vapour pressure for appreciable quantities of it to evaporate. On mixing with the much cooler atmosphere the vapour will condense to form visible aerosol particles in much the same way that condensing water gas forms the visible aerosol particles called 'steam'. If one extrapolates from the known features of the condensation of water and other substances to form aerosols, it seems reasonable that the lava vapours may condense either as vitreous droplets or as small crystalline particles.

If particles can condense from the gas phase over lava fountains and lakes, similar processes might take place in a phreatic eruption; some gaseous components from the hot lava may be present in the gas phase of the high-velocity eruption which will condense to form an aerosol when cooling takes place by adiabatic expansion or by mixing with the atmosphere. While the larger particles of tephra in a volcanic eruption are undoubtedly formed by mechanical disruption of lava, it appears quite possible that some of the smaller tephra particles of an eruption result from the condensation and growth of aerosol particles from the vapour phase. Thus the cloud-forming process in the phreatic eruption may be similar to that occurring in the screening smoke generators developed by Langmuir and Schaefer[2]. In these a high boiling petroleum oil was vaporized along with water and then caused to escape at high velocity into the atmosphere where it condensed as an aerosol.

All the evidence suggests that the spectacular meteorological optical phenomena, such as vividly coloured sunsets and Bishop's rings, associated with volcanic eruptions are the result of very small particles. Since the optical phenomena extend over large portions of the globe and persist for months or even years[3], the particles must be so small that they settle very slowly. deBary and Bullrich[4] state that in order to have Bishop's rings it is necessary for these to be present: (*a*) an abnormally dense layer of aerosol particles with almost identical radii of 0·3–0·4μ at a constant altitude over a wide area in the vicinity of the observer; (*b*) a concentration of aerosol particles 5–10 times greater than usual. The aerosol particles are so small and so uniform that it appears unlikely that they result from mechanical disruption. It seems far more probable to us that this class of particulate matter is the result of condensation from the vapour phase.

Thus it seems likely that the formation and properties of the high-temperature clouds of the volcano are similar to ordinary atmospheric water clouds. It would therefore be worthwhile to obtain quantitative information concerning the partial pressures of the lava vapour during volcanic eruptions. If the vapour pressures are comparable with the partial pressures of water vapour in the atmosphere, a significant portion of volcano clouds and of the small tephra particles may be formed by a condensation and coagulation process similar to that which occurs in water clouds. Conceivably, if the partial pressure of the lava components is sufficiently high, the heat released by the formation of liquid or solid cloud particles may be of significance in the formation of nuées ardentes.

We have carried out some preliminary laboratory experiments that confirm that aerosols are produced when hot lava evaporates into the atmosphere. We have observed smoke to form when basalts are melted on an electrically heated wire filament or in a crucible. Basalt heated in air to about 1,400° C in a platinum crucible produced a light brown condensate on a water-cooled glass flask above the crucible (Fig. 2). A mixture of basalt and dunite heated to about 1,500° C under reducing conditions (in a graphite crucible in argon) produced a 'smoke' containing dark brownish-grey structures resembling cobwebs. X-ray diffraction of these 'cobwebs' indicated the presence of silicon, SiO_2, Mg_2Si and MgO. X-ray fluorescence of both deposits showed strong evidence of potassium, calcium, iron and silicon.

It is apparent that, in the processes we observed to occur over Surtsey, the ambient atmosphere is of dominant importance. The presence of an atmosphere affects the formation and deposition of aerosols in at least four ways: (1) it maintains a high enough concentration of the lava

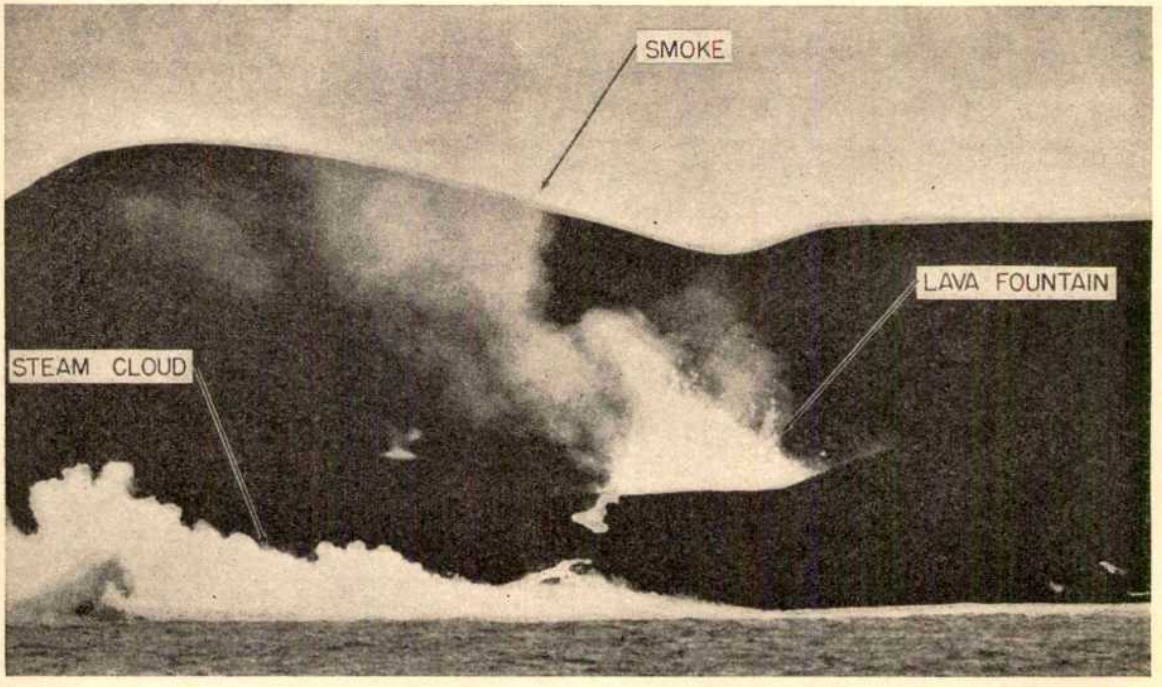

Fig. 1. View of the new island, Surtsey, with cloud of dark smoke above lava fountain. White plume in foreground is steam cloud caused by contact of lava flow with sea water. (Photo by Sigurgeir Jónasson)

gas to allow sufficient supersaturation for particle formation by condensation; (2) it causes sudden quenching of the hot gases by mixing and expansion; (3) it prevents rapid falling of the particles; (4) it transports the particles by the wind.

Because of the great influence of the atmosphere on the behaviour of hot lava vapours, it is interesting to consider what sort of processes might take place in Nature under conditions of very low atmospheric pressure such as those which exist on the Moon. Here, when silicates vaporize from volcanism or other causes, the results will be different. At these very low pressures the mean free path of the molecules will be large and the chances of their coming together to condense to form a particle will be negligibly small. Using an analysis similar to that of Watson *et al.*[5] it can be shown that on the Moon most of the species evaporating from the surface of a rock melt will move at less than escape velocity and will return to the Moon's surface. Here they may condense to form a structure that is frost-like or dendritic in character. Following their analysis it can also be shown that the average distance a molecule of metallic oxide evaporated from a melt will travel before landing on the Moon's surface will be of the order of several hundred kilometres. This ensures relatively uniform deposition over a substantial fraction of the surface from even a small area of melt.

To investigate effects of vacuum we performed a simple experiment by heating about 1/5 g of basalt to about 1,200° C in a vacuum of 10^{-4} torr for a few minutes. This produced a dark brown film several microns thick on a microscope slide suspended above the melt. Again X-ray fluorescence showed strong lines of potassium, calcium and iron. No good X-ray diffraction peaks were observed from the thicker parts of the deposit, but under the optical microscope small particles showing apparent crystalline outlines were observed on the thinner parts of the film (Figs. 3 and 4). Dark-field electron microscopy of thinner parts of the film from the slide showed the presence of crystals ranging in size from several hundred to several thousand angstroms.

The observed photometric properties of the surface of the Moon are consistent with the idea that vapour deposition may have played a part in its formation. Hapke[6] has summarized the photometric characteristics of the entire visible portion of the lunar surface, drawing particular attention to the low albedo, strong back-scattering, unusual polarization properties, and brownish-grey colour. He concludes that the only materials that would be photometrically consistent with the observations are some types of vegetation, non-metallic whiskers and dark, finely divided particles. There can be no vegetation because of the lack of atmosphere. He suggests that although whiskers might be formed by the combined effects of sputtering by the solar wind and condensation of material vaporized by micrometeorites, they are unlikely to survive under repeated meteorite bombardments. Hapke concludes that the surface must be covered with a layer of pulverized rock powder 10μ or so in size which has been "darkened by exposure to solar radiation or some other agent and arranged by micrometeorite bombardment into a porous material with a bulk density only one-tenth that of solid rock". A comparison of Fig. 2 with Hapke's[7] photographs of a fine powder with the required 'fairy-castle' packing shows a strong resemblance. Simple preliminary measurements indicate that our light-coloured air-deposited material also exhibits a strong back-scattering peak. The materials evaporated under less oxidizing conditions in a graphite crucible in argon or in a vacuum showed considerable darkening as would be expected.

Fig. 2. Photomicrograph of condensate formed on cold surface in air above crucible containing molten basalt at about 1,400° C

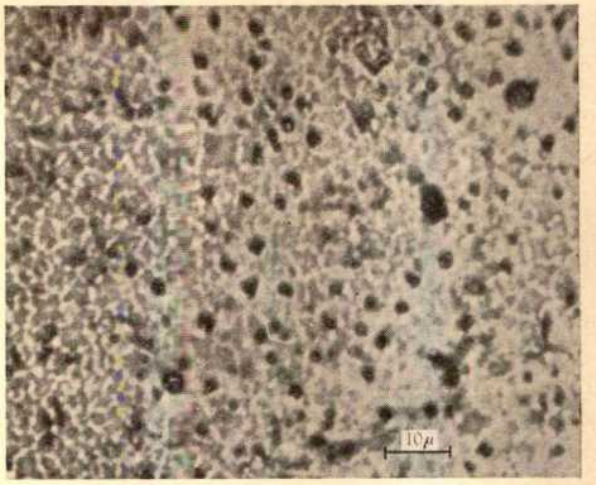

Fig. 3. Photomicrograph of thin condensate film formed on glass held for several minutes in a vacuum above molten basalt at about 1,200° C

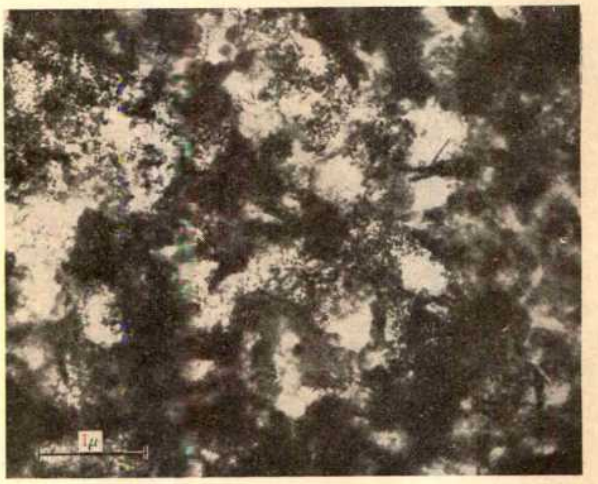

Fig. 4. Transmission electron photomicrograph of that area of the film shown in Fig. 3 from which electron diffraction pattern indicating crystallinity was obtained. Note the similarity between the fine granular structure shown in this figure and the much coarser structure of the air-deposited material of Fig. 2

It thus appears that the volcanic evaporation–condensation mechanism should be added to micrometeorite impact and solar wind sputtering as a possible factor contributing to the evolution of the visible portion of the Moon's surface.

From our observations at the volcano and in our laboratory we conclude that the formation of particulate matter by the condensation of vaporized components of hot lava is important in the origin of terrestrial volcanic clouds and atmospheric aerosols. The volcanic evaporation–

condensation mechanism may also be of importance in the formation of the surface of the Moon.

We thank the Manned Spacecraft Center of the National Aeronautics and Space Administration, the Geophysics Branch of the Office of Naval Research, the Atmospheric Sciences Program of the National Science Foundation and Arthur D. Little, Inc., for the support that made this work possible.

A PACKAGED PLANT GROWTH CABINET WITH HIGH AND UNIFORM INTENSITY OF ILLUMINATION

By G. A. CARPENTER
The National Institute of Agricultural Engineering, Silsoe, Bedford

IT is becoming normal practice for a research institute or university department concerned in any way with the growth of plants to construct facilities for growing plants under controlled conditions. The trend in countries other than the United Kingdom has been to construct a phytotron[1,2]—a large complex of rooms, cabinets and glasshouses situated at one site, using natural and artificial light. In the United Kingdom, the Agricultural Research Council has adopted the policy of helping to set up controlled environmental facilities of limited size at existing institutes and universities. While it is recognized that certain types of research demand a 'walk-in' room, wind-tunnel or other specialized type of chamber, it was considered that a packaged 'reach-in' cabinet would fulfil a substantial proportion of the needs. The Agricultural Research Council has therefore provided support for an investigation at the National Institute of Agricultural Engineering of the design principles of an artificially-lit cabinet (Fig. 1). As a preliminary to this investigation, a survey was undertaken of more than 100 organizations considered to be potential users in order to find out the main requirements for controlled environment facilities. Several aspects of the final design of the cabinet, for example, the chosen range of operating temperatures, are a direct result of the survey. The present position is that the cabinet has been developed in conjunction with R. K. Saxton (Sax-Air), Ltd., and fifty are being made by this company. About thirty cabinets have so far been installed at eight research institutes and university departments.

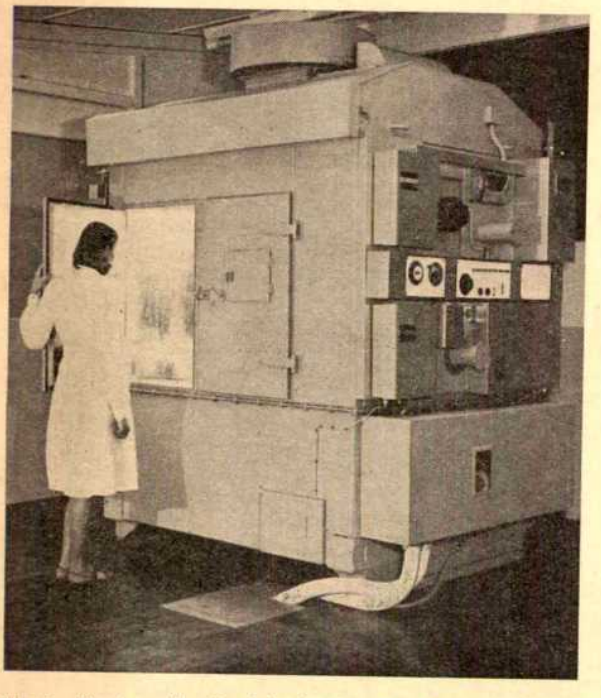

Fig. 1. Plant growth cabinet developed at the National Institute of Agricultural Engineering

In the past, designers of growth cabinets have used a constant temperature room as a starting point and have added illumination; the association of plant growth rooms with basements is partly a result of this expedient. More recently, there has been a tendency to use packaged cabinets or even rooms as free-standing entities having greater independence of the building structure. Such an approach gives more room for plant handling, lamp access and equipment maintenance, coupled with greater flexibility for major alterations or even entire removal to another building. Many of the problems in design apply equally to a cabinet or a room, these being best regarded as designs with different or complementary uses rather than rigid alternatives; for example, a room is particularly suited for prolonged measurements *in situ*, or for growing large arrays of plants.

For a growth chamber to be satisfactorily designed, it is essential for the designer to be aware of the needs of the user, but the latter should also be aware of the engineering, physical or economic implications of his requirements—in short, an understanding is needed between the engineer and the biologist. Examples of this can be given: should a user decide that temperatures below 5° C are not required in a cabinet, then, by avoiding de-frosting problems, a significant increase in operational simplicity is achieved. Similarly, a user, in specifying the accuracy of control of temperature and humidity he requires, must ensure that this is compatible with the dependence of relative humidity on temperature. In the present state of knowledge, the relative merits of certain aspects of the design of a growth chamber are still not resolved; for example, direction of air movement and its velocity.

It is possible to define an ideal growth chamber in terms of what occurs in natural conditions or semi-natural conditions such as in a glasshouse; however, this is misleading, because most natural environments tend to fluctuate widely and any predetermined environment is artificial since it can only approximate to a condition or combination of conditions that exists periodically in a natural climate. Three criteria appear to be important: conditions should be uniform in space and time; conditions should be defined and reproducible; and plants grown in this environment should not be too dissimilar from ones grown in a typical natural climate.

There are certain design problems which are peculiar to plant growth chambers. First, the highest possible uniform light intensity must be provided over the whole experimental area, thus eliminating use of either the ceiling or the walls or doors for any purpose likely to obstruct light, and also imposing a substantial heat load on the air-conditioning system. Secondly, plants modify the composition of the atmosphere by transpiration of water and exchange of carbon dioxide, thus necessitating

air conditioning and fresh-air exchange. Thirdly, plants exhibit a large change of size in a short time which calls for a design that permits the conditions to remain uniform without continual adjustment of floor-level.

In the cabinet to be described, first advocated by Morris[3,4], the problem of providing a high intensity of light with good uniformity in time and space was solved in two ways: by the provision of a self-contained lighting unit; and by using this lighting unit in combination with specularly reflecting walls on the plant chamber to produce a rectilinear-box, artificial, overcast sky.

The lighting unit consists essentially of a box containing fifty-six 5-ft. fluorescent tubes arranged in two tiers; this arrangement gives 35 per cent more light than a conventional close-packed single tier[5]. The lamps are surmounted by a white reflector. Under these conditions, plain lamps are superior to those with an internal reflector[6]. Lamps arranged in this manner require forced-draught cooling which is provided by an axial-flow fan above the unit, air being sucked in through filters at the end of the lamps and passing through holes near the centre of the overhead reflector to the fan and thence to the atmosphere. Because the light output of this kind of lamp is dependent on temperature, the lamps are cooled uniformly over the bank and compensation for variations in ambient air temperature is provided by a temperature-sensitive device in the top of the lighting unit which permits some of the air to by-pass the lamps for lower ambient temperatures. The lamps are enclosed beneath by a double-glazed 'Perspex' ceiling; a screen of some kind is essential in order to separate the air streams conditioning the lamps and plants, respectively, thus making possible the independent control of the temperature environment of both lamp and plant. In addition, if double glazing is used, long-wave heat radiation from the lamps is reduced by two-thirds and this reduces the load on the air-conditioning system in the plant chamber. 'Perspex' was chosen in preference to glass because it is light in weight and not easily broken; experience has shown that with reasonable care it does not become scratched, nor does it 'age' under this type of irradiation. Rather surprisingly, the loss of light transmission attributable to the double-glazed ceiling is only about 6 per cent, due to multiple reflexion between the ceiling and the light source.

A rectilinear-box, artificial, overcast sky is characterized ideally by uniform flux density of light in all directions in the upper hemisphere, although in practice the best reflecting materials do not achieve this[6] and approximate as regards sky luminance to a real overcast sky[7]. The cabinet dimensions were chosen so that the plant floor was a square of 1·37 m side with the lighting unit overlapping by 8 cm on all sides. The walls were lined with metallized polyethylene terephthalate up to the ceiling. Under these conditions, the light intensity over three-quarters of the floor area does not fall below 95 per cent of the value at the centre of the floor; the lowest value of 92 per cent occurred in the corners. The light intensity at floor-level (112 cm from ceiling) is 75 per cent of that at ceiling-level.

The quality of illumination raises several points of interest to botanists. First, considering only the wavelengths 0·3–0·75μ, the intensity of illumination is only one-third of midday summer sunlight. However, the daily integral of light energy incident on the floor of the cabinet, using an 18-h day-length and a realistic schedule of lamp group replacement[8], reaches the average daily integral of light energy in the open for the month of June in the United Kingdom—averaged over a period of 5 years (Fig. 2), namely, 198 cals cm^{-2} per day. Furthermore, the light in the growth cabinet is diffuse, coming from all directions above the horizon, and might be expected to be utilized by plants more effectively than the highly directional light occurring on bright days out of doors. Thus, although there is likely to be a demand for still higher intensities, the cabinet, in terms of growth-rates, can give a performance comparable with that out of doors in summer. Secondly, per unit of light energy in the photochemically active range (0·3–0·75μ), sunlight contains one and a half to two times the total radiant energy than does the lighting in the cabinet. Thus, for a given growth-rate, transpiration is likely to be considerably less under cabinet conditions than under natural illumination. Thirdly, the 'overcast sky' provides a directionally defined type of illumination which can be repeated and is uniform over the whole of the floor. Because of the reflecting walls, guard plants are unnecessary if the outer row of plants is a 'half-pot spacing' from the walls, an effect illustrated in Fig. 3.

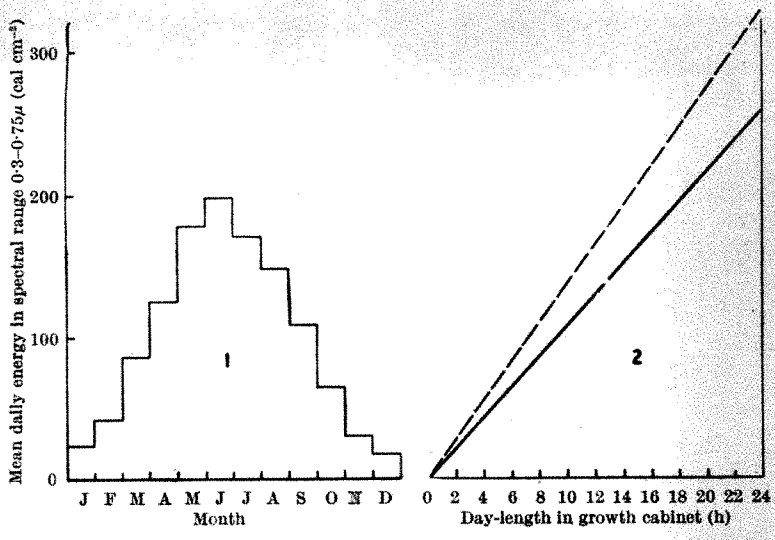

Fig. 2. (1) Variation of mean daily light energy with time of year at Kew Observatory. Average for 1956–1962 inclusive. Values are for total radiation × 0·47. (2) Variation of daily light energy with day-length in the plant growth cabinet. Broken line is for new lamps giving 0·23 cal cm^{-2} min^{-1} of light energy. Continuous line is for group replacement of lamps (1/5 every 1,000 h) giving 0·18 cal cm^{-2} min^{-1} of light energy. Measurements taken 112 cm from lamps

The aspects of design relating to air conditioning proved unexpectedly to present greater difficulties than for illumination. The area occupied by plants has to be a large proportion of the total floor area occupied by the cabinet; this results in severe problems related to the aerodynamics of turning and expanding the air flow. Furthermore, it is desirable to limit air velocity to below 100 ft./min and this produces unavoidable gradients of temperature and moisture content of the air as it passes through the chamber. However, with uniform distribution of air velocity, such gradients can be measured, calculated and controlled. Vertically upward air flow was adopted in preference to horizontal, since it ensures similar conditioning of all plants. It has advantages over vertically downward flow, since it permits the use of the space beneath the plant floor for obtaining a uniform velocity distribution through the plant canopy despite turning the air flow through 180° and expanding the duct area twenty-fold. It also means that the reflecting walls can be complete on all sides apart from a narrow exit slot along the top of one wall. Although Joffe[9] has expressed concern over the existence of stagnant air pockets above plants when using vertically upward flow, neither inspection of smoke trails nor the determination of velocity distribution in different horizontal planes produced evidence of stagnation. The characteristics of the air distribution system will have a bearing on this, and

Fig. 3. Visual illustration of the lighting principle used in the cabinet. 25 pots of *Helxine solieroliì* are shown inside a cube of size 68 cm with wall of glass mirror

there is little resistance to air flow inside the plant chamber. Covering the floor with close-packed 3·5-in. diam. pots has no detectable effect on volumetric air throughput, and streamline flow is maintained over the remaining unobstructed area of the floor, at a correspondingly increased linear velocity.

For a reasonably airtight cabinet operating on a closed air circuit, continuous release of moisture from plants in the chambers permits control of humidity by continuous condensation on a cooling coil of controlled temperature, thereby limiting the dew-point. If the moderate air-velocity, and thus the air circulation rate, is also taken into account, the cooling and heating loads imposed by cooling the air to dew-point and re-heating to dry-bulb are not prohibitively large. Such a system was therefore adopted in this cabinet. The need to control cooling-coil temperature made it essential to use secondary refrigeration and a proportioning controller. It is interesting to note that plant transpiration rate influences the design of the cooling coil. In principle, a silent pump on the cabinet continuously pumps coolant through a cooling coil, and coolant at 33° F is available from a reservoir remote from the cabinet. The temperature of the cooling coil depends on the position of a servo-operated valve which mixes coolant from the reservoir with warmer coolant from the coil. The air is re-heated by means of an electrical heater fed from the output of a servo-operated transformer. Both temperature and humidity depend for control on measurement of temperature, and the sensing elements are therefore completely trouble-free, being dry-bulb resistance thermometers. The controllers are two-term electronic instruments. The main fan is variable in speed. The refrigeration unit consists of a packaged chiller connected to the cabinet by two pipe-lines. Up to three cabinets can be supplied from a single refrigeration unit.

The variation of air temperature is less than ±0·5° C with time and ±0·75° C over a horizontal plane. When the lights are on, leaf temperature will be subject to a temperature gradient in a vertical direction. The workable temperature range of the cabinet is 4°–30° C. Relative humidity is uniform in time to about ±2 per cent provided adequate evaporating surface is provided either by plants or by a special wick; this figure will vary with actual temperature and humidity.

Although the cabinet consists basically of a steel structure of special design, most of the components used are available commercially. The special design, in addition to incorporating the features already mentioned, gives good accessibility to components, permits breakdown into five sections for installation in buildings with restricted access, and also gives scope for modifications by users. The cabinet also has a comprehensive built-in alarm system.

I thank Mr. L. G. Morris for his technical advice, and Dr. D. Rudd Jones for his sustained interest in this project. I also thank the Director-General of the Meteorological Office for permission to use records of total daily radiation.

WHAT'S IN A VIRUS NAME?

By Dr. A. J. GIBBS and Dr. B. D. HARRISON
Rothamsted Experimental Station, Harpenden, Hertfordshire
AND
Dr. D. H. WATSON* and Prof. P. WILDY*
Department of Virology and Bacteriology, University of Birmingham

Inadequacy of Names in Use at Present

VIROLOGY has advanced greatly in recent years, but virologists have had little success in devising a satisfactory way of naming the entities they study. Most virus names now in use are essentially arbitrary and have to be learned by rote because they give little indication of the properties of the virus named. This applies to vernacular names such as 'tobacco mosaic virus' and even more so to semi-numerical names of the type '*Nicotiana* virus 1', which gives only half as much information as its corresponding vernacular name. There have been several, largely unsuccessful, attempts to introduce latinized binomial names for viruses. This type of nomenclature has been particularly effective for those animals and plants that reproduce sexually, but less so for those that reproduce mainly by other methods.

Some of the shortcomings of latinized binomials are indicated by the chaotic situation which has resulted from

* Members of the Medical Research Council Virus Group.

their use with a non-phylogenetic, but hierarchical, classification of bacteria. Indeed, when the basic unit in this classification, the 'microbial species', is considered by the curator of the British National Collection of Type Cultures to be a 'macromyth'[1], it is not surprising that latinized binomial names have proved unsatisfactory for such organisms. It is also becoming more widely recognized that Latin is no longer internationally well understood[2]. The latinized binomial system may have been unsatisfactory in practice for bacteria because of the rules that have governed its use, rather than because it is intrinsically bad, but we think that if applied to viruses it will give similar or even worse results.

What, then, can be done? Criticism of existing practice is most helpful when accompanied by suggestions for a better system, but before making our suggestions we wish to discuss the aims of nomenclature and its basis in classification.

Aims of Nomenclature

If the only purpose of virus nomenclature is to provide each virus with a specific label, then it is necessary only to devise a series of unique epithets "quaint enough to be unforgettable"[3]. However, a name would be far more useful if it indicated some of the properties and thus the affinities of the virus. Ideally a name should be: (1) simple, easily understood and usable by people speaking different languages; (2) indicative of the properties of the virus named; (3) unchanging. The main difficulty is to devise names that are unchanging, or rarely change, and yet indicate what is known of the properties of the virus named, when this is likely to increase greatly as the result of future research.

The solution we suggest is to use a name made up of two functionally different parts, one part a convenient and unchanging label, which would be the vernacular, or trivial, name, and the other part an internationally agreed code indicating the present state of knowledge of the properties of the virus. The idea of a code has recently been considered both for viruses[4] and for bacteria[5] but not developed in detail, and for enzymes a similar code has been in use since 1961. Such a code will best indicate the properties and thus the affinities of the virus if based on a virus classification, and so, before describing our ideas for a code, we shall discuss virus classification.

Classification of Viruses

The aim of virus classification is to make an ordered arrangement of viruses that will indicate their similarities and differences. Viruses can of course be classified on the basis of any features. However, if there is any point on which virologists are at all likely to agree, it is that we now need a general rather than a special classification. Such a classification has two main uses: (1) To predict the unknown properties of a virus by analogy with the known properties of similar viruses. This is of value both in virus identification, where the identity of a virus may be more readily predicted and more speedily established by studying the most convenient and most clearly differentiating properties suggested by a classification, and also, when a 'new' virus is found, to predict by analogy some of its properties. (2) To form a basis for virus nomenclature.

One of the great debating points of taxonomy in recent years has been whether or not more importance should be attached to some characters than others. 'Important' characters are supposedly recognized because they are either basic or indicate phylogeny. The phylogeny of viruses, however, is at present a matter for speculation only, and though nucleotide sequence may perhaps be the only functionally basic character of a virus, at present we neither know nor could interpret such a sequence. Alternative characters must therefore be used. The hierarchical systems for grouping viruses proposed by Holmes[6], Hansen[7], Cooper[8], and by Lwoff, Horne and Tournier[4], have required the classifiers to decide on the relative importance of these alternative features. We can think of no satisfactory way of estimating the relative importance of different characters, and therefore consider it essential to follow the principles of Adanson[9], who suggested that all known information should be used, and that all characters should be considered equally important. Using these principles we will obtain a phenetic classification of viruses, that is, one based on the similarity of their overt properties. This does not mean that the classification may not have some phylogenetic significance, for the classifications of higher plants and animals used at present were phenetic in origin and have only later been shown to agree, in parts, with phylogeny.

Now that electronic computers exist, classifications using Adanson's principles can be made easily and accurately[10]. The first attempt to classify viruses in this way[11] had limited success because, if this type of classification is to have much worth, it must be based on at least sixty equally weighted independent characters[12], and at that time too few characters were known. A quick survey of the most recent literature on 500 or so of the best-known viruses infecting vertebrates, insects, seed plants and bacteria shows that we still have less than 5 per cent of the information needed. Therefore, although a general classification of viruses on Adansonian principles can be begun now, it still can be only crudely quantitative. Plainly, we cannot yet classify viruses objectively and rationally, but we should expect to be able to do so one day. In the meantime, if we are to do anything at all, we must make do with some more subjective approach, but it is imperative, and this is one of our principal points, that the temporary measures (both for classification and nomenclature) should in no way prejudice the evolution of a more satisfactory classification.

The Problem of Grouping

When we use the existing information on characters of viruses (for example, Table 1) to compare the viruses phenetically, we find that many arrange themselves in groups, but the difficulty is to decide how best to delineate these groups. We may illustrate our approach to this problem by the four examples given in Table 2. Whereas we distinguish the turnip yellow mosaic group of viruses from the squash mosaic group because the two groups differ in several characters shared by viruses within each group, we might not place poliovirus 1 and acute bee paralysis virus in separate groups because in this case the differences seem few.

Table 1. Some Characters to be used in classifying Viruses

(1) Viral components	
Nucleic acid	— DNA or RNA
	— single or double stranded
	— molar base ratio
	— molecular weight
	— percentage in particles
Protein	— No of different proteins in virus particles
	— enzymes in particles
	— other virus-induced proteins
	— serological relationships, as revealed by precipitation, neutralization and complement fixation tests
	— haemagglutinating properties
Lipid, Polyamine, etc.	— composition and amount
(2) Particle form	— shape
	— size
	— structure and symmetry of nucleocapsid
	— accessory structures
	— density
	— sedimentation coefficient
	— accessory particles; types and properties
(3) Stability of infectivity and particles	
	— temperature; thermal inactivation point
	— effect of chemicals, for example, ether
	— effect of enzymes
	— photo-reactivability
(4) Interactions with hosts	— site of growth in cell
	— tissue tropisms
	— pathological effects
	— host range; host taxa; no. of susceptible species
	— response to inhibitors of multiplication
(5) Mode of natural spread	— vector or not; type of vector; behaviour of virus in vector
	— own infection mechanism (phages, etc.)

The members of a group differ most in the fine details of host range and pathological effects. It would seem that these biological characters are not correlated with the other characters we have used for grouping.

The status of serology in such a system of groups warrants special mention, for many people believe that serology is the most, if not the only, useful character in virus classification. This attitude has perhaps arisen because serological relationships have been found so far only between virus isolates that share most of their properties. Therefore we find that, in a phenetic classification, viruses known to be serologically related are in the same group, though any one group may contain viruses that seem serologically unrelated. Serological tests, therefore, help not only to identify and group viruses, but also to distinguish between the members of a group.

Nomenclature of Viruses : Our Suggestions

The first part of the name, the vernacular part (for example, the list of names of plant viruses used by the *Review of Applied Mycology*[13]), would have the advantage that it is already widely used. Most such names indicate the disease with which the virus was first associated, and could be translated into other languages where this has not already been done.

The second part, the code or cryptogram, would indicate current information about the virus and might therefore frequently change. A cryptogram could be devised with many symbols, one for every character of the virus; this would give a shorthand summary of all the known properties of the virus, and would thereby give each virus a unique specification, but though it might be useful for a reference book it would be too cumbersome for general use as part of the name of a virus. Therefore we suggest an abbreviated type of cryptogram with only four terms. This would be sufficient to separate viruses into the groups already discussed here, or small collections of such groups. Table 3 shows the form of this cryptogram, and gives examples of the cryptograms of a few well-known viruses. The symbols are intended (where possible) to be suggestive of the characters they represent.

Although we have selected characters for the cryptogram that conveniently separate the groups of viruses recognizable at present, other characters may have to be substituted from time to time to take account of changes in classification. We emphasize that the cryptogram is not a part of the classification; it is a part of the name of the virus that reflects some aspects of the classification and indicates the state of knowledge of some of the properties of the virus.

In general, bacterial and vertebrate viruses will be most clearly differentiated from one another by the first three terms, for few of these viruses have vectors, whereas viruses of higher plants will mainly be distinguished by the last three terms because many of them contain single-stranded ribonucleic acid.

'Four-letter words' are often printed with some of their characters disguised by the symbol '*'. We suggest that this symbol be used in the cryptogram when there is no information on the relevant property, both when the property has not been studied, and also when in spite of study the property is not known, for to distinguish between the two possibilities would be difficult. A further tentative suggestion is that bold type should be used to indicate that the property has been determined on the virus in question, and, when the property can reasonably be assumed by analogy with a closely related virus, normal type be used.

A few of the cryptograms will, as already mentioned, relate to more than one of the groups of viruses obtained using the whole range of known characters. Thus both the turnip yellow mosaic group and the squash mosaic group of viruses would have the cryptogram

$$\frac{\mathbf{R}}{\mathbf{1}} : \frac{\mathbf{2}}{\mathbf{35}} : \frac{\mathbf{S}}{\mathbf{S}} : \frac{\mathbf{S}}{\mathbf{B}} \quad \text{(Table 2)}$$

To distinguish the individual groups in such collections would require a range of additional features, and because

Table 2. Properties of some Small Viruses

Property	Turnip yellow mosaic group of viruses	Squash mosaic group of viruses	Poliovirus 1	Acute bee paralysis virus
Type of nucleic acid	RNA	RNA	RNA	RNA
Strandedness	single	single	single	—
Nucleotide ratio (moles G : A : C : U approx.)	16 : 20 : 40 : 24 or 16 : 22 : 33 : 29	22 : 30 : 17 : 31	25 : 31 : 19 : 25	—
Molecular weight of nucleic acid in particles	$1{\cdot}8 \times 10^6$	2×10^6	2×10^6	—
% nucleic acid in particles	37	35	30	35
Appearance of particles	'spherical', 25–30 mμ diam., 32 major morphological sub-units	'spherical', 25–30 mμ diam., distinct polygonal outline	'spherical', 25–30 mμ diam., rounded polygonal outline	'spherical', 25–30 mμ diam., rounded polygonal outline
Sedimentation coefficient (S)	106–121	103–125	158	160
Sedimentation coefficient of naturally occurring accessory particles (S)	49–56	84–100 and 54–60	—	80
Thermal inactivation point (10 min)	75° C	75° C	62° C	75° C
Serological relationships	The TYM group includes two sub-groups of viruses, with distant serological relationships between viruses within each sub-group, but none to viruses in the other sub-group	Distant serological relationship between all members of the SM group where this has been tested	†	†
Mode of spread	Beetle vector	Beetle vector	No vector	No vector
Host range	Seed plants: moderate range of species	Seed plants: moderate range of species	Vertebrates: primates only	Invertebrates: bees only
Pathological effects	Mostly mosaics	Mostly mosaics, or mottles, some hosts give necrotic local lesions	Inapparent; or necrosis of gut cells, more rarely of nerve cells	Inapparent; or necrosis of nerve tissue
Number of phenetically similar viruses	6	5	—	—

† Poliovirus 1 and acute bee paralysis virus are unrelated serologically.

Table 3. THE CRYPTOGRAM

ARRANGEMENT

$$\frac{\text{Type of NA}}{\text{Strandedness}} \cdot \frac{\text{M.W. of NA}}{\%\ \text{NA}} \cdot \frac{\text{Outline of particle}}{\text{Shape of N.C.}} \cdot \frac{\text{Hosts}}{\text{Vector}}$$

EXPLANATION AND SYMBOLS†

Type of NA	R, RNA; D, DNA
Strandedness	Strandedness of nucleic acid 1 = single, 2 = double
M.W. of NA	Molecular weight of nucleic acid in millions
% NA	Percentage of nucleic acid in infective particles
Outline of particle	S, Essentially spherical E, Elongated with parallel sides, ends not rounded U, Elongated with parallel sides, end(s) rounded T, Having a tail X, Complex or none of above
Shape of N.C.	Shape of nucleocapsid S, Essentially spherical E, Elongated with parallel sides, ends not rounded U, Elongated with parallel sides, end(s) rounded X, Complex or none of above
Hosts	Kinds of host infected V, Vertebrate; F, Fungus I, Invertebrate; B, Bacterium S, Seed plant; A, Actinomycete
Vector	Kinds of vector 0, Spreads without a vector; no vector known A, Aphid (Insecta, Hemiptera, Aphididae) B, Beetle (Insecta, Coleoptera) C, Mealy-bug (Insecta, Hemiptera, Coccidae) D, Fly (Insecta, Diptera) E, Mite (Arachnida, Eriophyidae) F, Fungus (Fungi) G, Tingid bug (Insecta, Hemiptera, Gymnocerata) I, Tick (Arachnida, Ixodoidea) L, Leaf-, plant- or tree-hopper (Insecta, Hemiptera, Auchenorrhyncha) N, Nematode (Nematoda) S, Flea (Insecta, Siphonaptera) T, Thrips (Insecta, Thysanoptera) W, White-fly (Insecta, Hemiptera, Aleyrodidae)

EXAMPLES

Herpes simplex virus	$\frac{D}{2} \cdot \frac{74}{*} \cdot \frac{S}{S} \cdot \frac{V}{0}$
Influenza virus *A*	$\frac{R}{1} \cdot \frac{2}{1} \cdot \frac{S}{E} \cdot \frac{V}{0}$
Coliphage *T2*	$\frac{D}{2} \cdot \frac{120}{30} \cdot \frac{T}{X} \cdot \frac{B}{0}$
Tobacco mosaic virus	$\frac{R}{1} \cdot \frac{2}{5} \cdot \frac{E}{E} \cdot \frac{S}{0}$
Clover wound tumour virus	$\frac{R}{2} \cdot \frac{*}{*} \cdot \frac{S}{S} \cdot \frac{IS}{L}$

† Bold type could be used to indicate that the property has been determined on the virus in question, and, when the property can reasonably be assumed by analogy with a closely related virus, normal type could be used.

we do not wish to indicate these in the cryptogram and make it more complex, we suggest that such groups should be distinguished in another way. One possibility would be to follow the four terms of the cryptogram with a name specific to the group, for example, 'TYM-group'. Names could be coined where they do not already exist, as for example with most plant or insect viruses. Alternatively, instead of a group name an arbitrary symbol, for example, a Greek letter, could be used (α, β, γ, etc.).

The cryptogram would thus specify the group to which a particular virus belongs. To specify individual viruses, an arbitrary number could be assigned to each member of each group. This would help to indicate synonymy between different vernacular names in any one language and between those in different languages, for example

Tobacco ringspot virus
Tobacco ring spot No. 1 virus
Tobacco virus 10
Annulus tabaci
Tabakringfleckenvirus

$$= \frac{R}{1} \cdot \frac{2}{35} \cdot \frac{S}{S} \cdot \frac{S}{N} : \text{NEPO group, 3}$$

Where such numbers already appear in the vernacular name, for example, human adenovirus 5, they would of course be unnecessary in the cryptogram.

Approval of Names

Although the four terms of the cryptogram would be decided simply on the basis of experimental work, decisions on which viruses should be included in any one group of phenetically similar viruses are less straightforward, and the numbering, if any, of viruses within a group is arbitrary. We therefore suggest that an international body should be responsible for these decisions. The proposed International Committee for Nomenclature of Viruses is the obvious choice. Possibly sub-committees could be set up to consider which viruses should be grouped together, and as the result of their recommendations, approved lists of vernacular names, together with the appropriate cryptograms, group names and numbering within the groups, distributed at regular intervals.

The advantages and disadvantages of the system of nomenclature which we propose (vernacular name together with a cryptogram based on an Adansonian classification; VAC system) are best shown by comparing it with another, such as the one using latinized binomials based on a non-phylogenetic hierarchy of 'basic' characters (LB system).

One advantage of the LB system would be that the names could be relatively short and easy to memorize, whereas the VAC system would produce a more cumbersome 'name', but this is no great disadvantage, for in the usual type of scientific research paper the code part would be used only once to define a virus. The LB system would introduce yet another set of names to be learnt, for the vernacular names would undoubtedly still be used. In our proposed system, existing names would continue to be used, and only a few symbols would have to be learnt to interpret the cryptogram, and these symbols would, moreover, be used for all viruses.

The LB system is rigidly based on the characters chosen to determine the form of the hierarchy of taxa: divisions, orders, families, etc. If one of these characters should be found to be unsatisfactory for some reason, then part or all of the hierarchy might collapse, depending on the 'importance' of the character, and names would have to be changed or redefined, whereas in the more flexible VAC system only one symbol in the cryptogram would change.

With the VAC system a 'new' virus can be named as soon as it is found, and its vernacular name need never change. Its cryptogram will become more complete and perhaps change as its properties are determined, and the cryptogram will clearly indicate some of its known properties, those assumed by analogy and some of those not known. By contrast, in an LB system, someone will have to make the purely subjective decision about whether enough is known about a virus for it to be placed in the hierarchy and invested with a name, and once the virus has been named only the expert will know the adequacy or inadequacy of the information on which the name was based. Therefore with an LB system we may find many viruses, which are named on inadequate information and which will later have to be renamed, and/or many viruses will remain unnamed because not enough is known about them.

It is perhaps true that the VAC system is primarily a system helpful to the practising virologist, whereas the main outcome of adopting the LB system may be that virus taxonomists are kept happy and occupied.

Our main points can therefore be summarized as follows:

(1) The names of viruses in use at present are inadequate.

(2) The disadvantages of latinized binomials based on a non-phylogenetic hierarchical classification greatly outweigh their advantages.

(3) Virus nomenclature should be based on a general classification made using the principles of Adanson. Any system adopted now should not prejudice future developments.

(4) We propose a nomenclature in which an unchanging vernacular name is, where necessary, accompanied by a cryptogram indicating present knowledge of several of the properties of the virus, and its affinities.

(5) As a basis for discussion, a cryptogram using four terms is described.

(6) The new names should be subject to approval by an international body.

NEWS and VIEWS

Nobel Celebrations in Sweden: Sir Lawrence Bragg, O.B.E., F.R.S.

The visit of Sir Lawrence and Lady Bragg to Stockholm for the Nobel Festival on December 10, 1965, at the invitation of the Nobel Foundation, was a unique event in the history of the Foundation. Sir Lawrence received his prize 50 years ago, and his visit was celebrated by a number of dinner parties and receptions. On December 9, Sir Lawrence gave the first Nobel Guest Lecture, taking as his subject the development of crystallography from its beginning to the latest crystallography of proteins. The Nobel Guest Lecture is a new innovation of the Foundation and is to be given each year by a distinguished laureate. Sir Lawrence's presence at the celebrations was very favourably commented on by many speakers at the celebrations, including the acting president of the Nobel Foundation, Mr. G. Söderlund, and the permanent secretary of the Swedish Academy, Dr. K. R. Geirow. In addition, on December 14, Sir Lawrence and Lady Bragg visited Uppsala University, where Sir Lawrence lectured on "Recent Advances in Protein Analysis". [A recent biographical note on Sir Lawrence was published on p. 353 of the July 24, 1965, issue of *Nature*.]

Civil Engineering in the University of Aston in Birmingham: Prof. M. Holmes

Dr. M. Holmes has been appointed professor of civil engineering and head of the new Department of Civil Engineering in the University of Aston in Birmingham (designate). In 1950 Dr. Holmes graduated from the University of Leeds with a B.Sc. degree in civil engineering, and in 1958 he was awarded a Ph.D. degree by the University of Bristol. He served for two years with the Royal Air Force as a flying officer, and then, after a short period in industry, he joined the staff of the University of Bristol as a lecturer in civil engineering. In 1960 he was appointed reader in civil engineering at the Bradford Institute of Technology, and since 1962 he has been on the staff of the Department of Civil Engineering at the University of Leeds, where he is at present a senior lecturer. Dr. Holmes has conducted research in plastic design methods for tall steel buildings and also into the study of beam to column connexions in precast concrete. He has published a considerable number of papers on a wide variety of civil engineering subjects. Dr. Holmes's appointment takes effect from May 1.

Physical Chemistry in the Bradford Institute of Technology: Prof. M. W. Roberts

Dr. M. W. Roberts has been appointed to the new chair of physical chemistry in the Bradford Institute of Technology. Dr. Roberts was educated at the Amman Valley Grammar School, Ammanford, and then at the University College of Swansea, University of Wales. He graduated in 1952 and carried out postgraduate research with Prof. K. W. Sykes in the field of surface chemistry. From 1955 until 1958 he was seconded from the United Kingdom Atomic Energy Authority as a Post-doctoral Fellow to the Imperial College of Science and Technology, where he collaborated with Prof. F. C. Tompkins in investigations of the nitridation of calcium. After this, Dr. Roberts held an appointment as senior scientific officer at the National Chemical Laboratory and worked on the mechanism of metal oxidation. In 1959 he was appointed lecturer in physical chemistry at the Queen's University of Belfast, where he continued his studies of the mechanism of surface processes and also collaborated with Prof. C. Kemball in catalytic investigations. In 1964 he was invited by the Czechoslovak Academy of Science to lecture at the Institute of Physical Chemistry, Prague.

Mathematics in the College of Aeronautics, Cranfield: Prof. A. Stratton

Mr. Andrew Stratton has been appointed professor and head of the Department of Mathematics at the College of Aeronautics, Cranfield. He will take up the appointment on March 1, 1966. Mr. Stratton is at present head of the Research and Assessment Group of the Weapons Department of the Royal Aircraft Establishment, Farnborough. He has served continually at the Establishment since he graduated in 1939; initially he was concerned with radio proximity fuses and in 1954 was made superintendent of the Instruments Division (later the Inertial Navigation Division), where he was responsible for research and development work in the fields of flight instrumentation and simulation, airborne digital computers, advanced navigation and attack systems and the theory and technology of inertial navigation. As head of the Research and Assessment Group of the Weapons Department, he has been responsible for the theoretical assessment of weapon systems and for an intra- and extra-mural programme of research in weapon technology. Mr. Stratton is the author of many publications dealing particularly with the presentation of information in aircraft and inertial navigation, and his mathematical interests are concerned with the integrating function of mathematical analysis in engineering and applied science. His external activities include the offices of chairman of convocation at the University of Exeter and member of the Council of the Institute of Navigation.

Thames Barrage Scheme

In a written answer in the House of Lords on December 20, Lord Lindgren stated that while a Thames Barrage Scheme would always have attractions, no decision on such a matter could be final. The Government's view was that the potential advantages of such a scheme, in respect of such matters as flood prevention and amenity, were heavily outweighed by its disadvantages, most notably in regard to the grave interference which a barrage would impose on the operation of the Port of London.

Computers for Research

In a written answer in the House of Commons on December 21, the Secretary of State for Education and Science, Mr. A. Crosland, stated that he had invited the Council for Scientific Policy and the University Grants Committee to set up a Working Group to undertake a full-scale review of the computer requirements of universities and Research Councils, which would lead to a new 5-year programme of procurement. The Working Group, of which Prof. B. H. Flowers was chairman, reported in July, and its proposals are designed to meet the growing need for digital computing facilities for research. The Group recommended that there should be regional computing centres at the Universities of London, Manchester and Edinburgh, with very large computers to which research workers from other universities and research institutions would have access. It recommends better computing facilities for individual universities and research establishments which would be compatible with the proposed regional computers, and the system would thus form an integrated whole. At present prices, implementing these proposals for new machines, equipment, buildings and extra operating staff is estimated to cost £20·5 million for universities and £9·3 million for Research Councils in 5 years, compared with an average rate of approved orders for computers from universities over the past 3 years of less than £500,000 a year (£1·2 million in 1964). The Government has approved generally the proposals of the Group, but it is proposed to implement the programme over 6 years instead of 5. In the first 3 years expenditure will be at the rate of about £3 million a year and orders will be placed as soon as possible. Most of the recommendations of the Group for Research Councils had high priority within the programmes of the Councils. Mr. Crosland added that he proposed to set up, in consultation with the University Grants Committee and the Council for Scientific Policy, a Computer Board, which would keep the programme under review and be responsible for ensuring the full utilization of the facilities provided in both the centres and the universities generally. The programme formed part of the plans announced by the Minister of Technology for developing the use of computers as an instrument of modernization and of economic advance. The success of this plan called for a wider use of computers in universities so that many more graduates could become aware of the capabilities of computers and be trained in their use.

University of the Air

In a written answer to a question in the House of Commons on December 21 asking the Secretary of State for Education and Science for his plans for founding a 'university of the air', Miss Jennie Lee, Joint Under-Secretary of State for Education and Science, stated that a university of the air would provide opportunities for obtaining degrees and other technical and professional qualifications through special television and radio programmes, reinforced by correspondence courses, residential courses, and tutorial groups. It would have its own administrative centre, but would utilize existing organizations, such as local education authorities, universities and the broadcasting authorities. Costs, channels and other implications were now being considered by the Government.

Mass Spectrometry Data Centre for Aldermaston

The United Kingdom Atomic Energy Authority, with support from the Office of Scientific and Technical Information, is to set up a mass spectrometry data centre at the Atomic Weapons Research Establishment, Aldermaston. The centre will undertake an investigation into the use of computers for chemical analysis by matching and evaluating mass spectra, which will start immediately. In a 6-month research period, different matching techniques will be tried in conjunction with the relevant computer programmes to find the most suitable system. Another investigation which will start immediately will be into modern methods of classifying and handling information with the view of producing a spectra reference and retrieval system. This should produce a method of quickly recognizing compounds from their spectra. During the course of 1966 a world-wide index to compounds and materials already examined by mass spectrometry will be developed. For a given compound or material the index will give information such as where to find its spectrum and possibly a bibliography, its molecular weight and molecular formula. A mass spectra holding and information service will also be developed during the coming year. These last two services will, in due course, become available to mass spectrometry users throughout the world. Aldermaston has one of the largest mass spectrometry units in Britain, together with advanced computing and information facilities, which will contribute to the establishment of this mass spectrometry data centre.

Royal College of Science : Research Report

The *Research Report of the Royal College of Science, 1962–65*, summarizes the main lines of scientific research in progress during the past 3 years in the seven departments of botany and plant technology, chemistry, history of science and technology, mathematics, meteorology, physics, zoology and applied entomology (Pp. 87. London: Imperial College of Science and Technology, University of London, 1965). Emphasis is laid on the increasing cost of research brought about by use of specialized and often costly instruments. There are no references to published work. (The Royal College of Science is one of the three constituent institutions of the Imperial College of Science and Technology: the other two being the Royal School of Mines and the City and Guilds College.)

Research and Development in the Electronics Industry

The main feature of *The National Institute Economic Review* (No. 34; November 1965) is a long article on research and development in the electronic capital goods industry, with substantial appendixes on sources and methods, statistical tables, references and lists of firms, organizations and individuals who assisted in the enquiry. Although the industry is one of the most labour-intensive, with a high ratio of fixed assets per man, about 60 per cent of world exports of electronic capital goods are from the United States, compared with 20 per cent from world exports of all types. This lead is attributed less to original inventions than to more rapid development of greatly improved models and more efficient technical service and marketing. The effect of the enormous scale of the military and space research and development programmes on this United States lead is questioned: some European countries also have large military programmes, and the ratio of total research and development expenditures to turnover in many European firms is as high as that of their United States competitors. There is some evidence that firms which have been heavily dependent on military work have a less satisfactory performance in exports and in the civil market. For some products at least, the scale of development work in European firms has been below the minimum 'threshold' necessary for effective competition on the world market. A high ratio of research and development expenditure can still be a low absolute figure if sales are low, and any number of firms with a scale of effort below the 'threshold' will be ineffective as they will be late in developing the new products essential for survival. Military and space programmes gave United States firms an advantage for some products where management was able to exploit and adapt the consequent experience and technique for the differing requirements of the civil market, but similar military programmes in

Europe are not necessarily the best way to counteract this competition. The selection of the major research priorities is a political choice, and if the main priority is economic growth, the United States advantage can probably be offset by much more ambitious civil research and development projects in such fields as industrial automation, a computer 'grid', and electronic teaching aids.

Biochemistry and Microbiology of Reproduction

World Health Organization Technical Report Series No. 313 embodies the report of a World Health Organization scientific group on the *Biochemistry and Microbiology of the Male and Female Genital Tracts* (World Health Organization. Technical Report Series, No. 313. Pp. 15. Geneva: World Health Organization; London: H.M.S.O., 1965. 3*s*. 6*d*.; 0.60 dollars; 2 Sw. francs). The report summarizes our knowledge of the chemistry and enzymology of the uterus; sperm transport, capacitation and the acrosome reaction; nidation; placentation and the chemistry and enzymology of semen. It also discusses the effects of compounds of cadmium, zinc and selenium on reproduction, and the effects of infection on reproductive activity. Research needs are indicated, with emphasis on determination of the time of ovulation in the primates and the reaction of the uterine tissues during the reproductive cycle and pregnancy. Emphasis is also laid on the importance of viewing the male and female components in reproduction as an integrated whole and on the need to extend investigations to a wider range of species.

The Royal Society and Nuffield Commonwealth Bursaries Scheme

Awards under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme have been made as follows: Dr. A. T. Casey, senior lecturer in organic chemistry, University of Melbourne, to enable him to use new techniques in the study of metal–metal bonding in inorganic compounds, particularly those of the transition metals, at University College, London, for a year from December 1965; Dr. A. R. H. Cole, reader in physical chemistry, University of Western Australia, to enable him to gain experience in high-resolution electronic spectroscopy, in Ottawa between April and September 1966; Prof. E. O. Hall, professor of metallurgy, University of Newcastle, New South Wales, to enable him to gain experience in the use of thin-film electron microscopy, at Cambridge for a year from February 1966; Dr. F. T. Last, of the Glasshouse Crops Research Institute, Littlehampton, to enable him to examine, in New Zealand, from April to September 1966, methods for elucidating the part played by different fungi in the brown root rot complex of tomatoes; Prof. E. R. Love, professor of mathematics, University of Melbourne, to assist him to continue work on integral equations and integral transforms, at Cambridge for three months during 1966; Dr. C. R. K. Murty, reader in physics, Andhra University, to enable him to learn experimental techniques for measuring relaxation time, at Nottingham for 4 months from April 1966; Mr. B. S. Newell, of the C.S.I.R.O. Division of Fisheries and Oceanography, Cronulla, New South Wales, to enable him to study the development and improvement of analytical methods for nitrogen compounds in the sea, at Plymouth from January to December 1966; Dr. N. Okafor, lecturer in microbiology, University of Nigeria, to enable him to learn techniques of food irradiation, at Cambridge for 4 months from June 1966; Dr. J. G. Ramsay, reader in geology, Imperial College of Science and Technology, London, to enable him to study the structural and metamorphic history of part of the Himalayan mountain chain, working at the University of Baroda, with field work in the Gujarat region and in the Kumaon Himalayas, between March and June 1966; Dr. B. P. Setchell, senior research scientist, C.S.I.R.O. Division of Animal Physiology, Parramatta, New South Wales, to enable him to work on the development of a technique for perfusing a mammalian testis isolated from the body, at Cambridge for a year from November 1966; Mr. M. D. Sutherland, reader in organic chemistry, University of Queensland, to assist him to become familiar with the techniques of tracer work as applied to biogenesis, at Manchester, and also to work at Cambridge, between February and August 1966.

European Molecular Biology Organization Grants

The European Molecular Biology Organization (EMBO) has received a grant of £240,000 from the Volkswagen Foundation in support of European co-operation in molecular biology. The grant is intended for both short- and long-term fellowships, for a small number of visiting professorships and for advanced courses and study sessions. The most novel feature will be the award of short-term, quickly available fellowships to allow investigators to collaborate with colleagues in other laboratories. For example, when a problem urgently requires a specialized technique available in only one particular laboratory, which may be in another country, the Organization will award a fellowship allowing the investigator to go and work there for a period of a few weeks. Post-doctoral fellowships will generally be awarded for a year. They will be given to young and promising research workers to allow them to work under the guidance of leaders in the field of molecular biology. Senior fellowships may be awarded at anything up to professorial level; for example, in order to help universities to stimulate the development of molecular biology. According to the rules of the Organization, applications will be evaluated solely from the point of view of the scientific excellence of the project, regardless of the nationality of the applicant or of his membership of the Organization, but exchanges between scientists working in different European countries will generally be preferred to projects involving a single country only. This is because the aim of the Organization is to promote molecular biology at a European, rather than a national, level. Further information can be obtained from the executive secretary of the Organization, Dr. R. K. Appleyard, University of Brussels, 67, Paardestraat, St.-Genesius-Rode, Belgium.

International Clearing House for Medical Terminology and Medical Lexicography

An International Clearing House for medical terminology and medical lexicography has been established, following a meeting of the Bureau of the Council for International Organizations of Medical Sciences. The establishment of such a House was recommended on November 18, 1965, by an international group of experts, convened in Paris by the Council, under the chairmanship of Prof. John E. Gordon. The World Health Organization and the United Nations Educational, Scientific and Cultural Organization were represented at the meeting. This group strongly emphasized in its report that medical terminology is in a confused state; in certain branches of medicine the situation is approaching chaos. Certain diseases have been discussed by medical scientists under no less than thirty different names, and many diseases are known, in the same language, under as many as ten or more entirely different names. Under such conditions, scientists cannot be certain whether or not they are talking about the same thing, and communication becomes more and more difficult. Research that costs time, effort and money may be largely in vain if the necessary information cannot readily be located in the scientific literature. Misunderstandings, potentially dangerous to the public, also arise from the confusion prevailing in medical terminology. The main task of the International Clearing House will be to stimulate learned medical societies to examine the problems of medical language, prune from

it unnecessary words, and adopt internationally acceptable terms and definitions. The Clearing House will also encourage proper scientific bodies to prepare medical dictionaries and will do everything possible to facilitate their publication and dissemination. It will collect information from all over the world on all activities regarding medical terminology and make it available on request to those interested. It will deal only with the five languages most commonly used in medicine at the international level, which were agreed to be English, French, German, Russian and Spanish. Further information can be obtained from Prof. M. Florkin, Council for International Organizations of Medical Sciences, 6 rue Franklin, Paris 16.

New Chromophoric Reagents for Labelling the Thiol Groups of Proteins

S. F. CHANG (Research Division, Parke-Davis and Co., Ann Arbor, Michigan) and Prof. I. E. Liener (Department of Biochemistry, University of Minnesota) have written to the Editor as follows: "We would like to correct our recent communication which described two new chromophoric reagents for labelling the thiol groups of proteins (*Nature*, 203, 1065; 1964). In preparing 4-phenylazo-2-chloromercuriphenol (compound I) it was stated that 1·14 g of *O*-chloromercuriphenol was dissolved in 30 ml. of 15 per cent potassium hydroxide prior to coupling with diazotized aniline. This should be corrected to read: '1·14 g of *O*-chloromercuriphenol was dissolved in a minimum amount of 15 per cent potassium hydroxide at room temperature and diluted to 30 ml. with distilled water'. The remainder of the procedure is unchanged. Although compound II (4-(*p*-nitrophenylazo)-2-chloromercuriphenol) may also be obtained by this procedure, the following alternative method is recommended: Dissolve 1·0 g of *O*-chloromercuriphenol in 100 ml. of 70 per cent ethanol, filter, and add 15 g of sodium acetate to the filtrate. Cool to −2° C. To a solution of 0·42 g of *p*-nitroaniline, 4 g of cracked ice, and 12 ml. of concentrated HCl was added dropwise 0·21 g of sodium nitrite dissolved in 3 ml. of distilled water. The diazonium salt solution was cooled to −2° C and added dropwise to the solution of *O*-chloromercuriphenol. After the mixture had been stirred for 1·5 h in an ice bath, and diluted to 400 ml. with cold distilled water, the orange-yellow precipitate was collected by filtration and dried over $CaCl_2$ *in vacuo* overnight. This compound could be further purified by recrystallization from hot ethyl acetate or by passage through a column of acid-washed alumina (Merck) with ethyl acetate as the solvent. A red-coloured impurity was retained on the column, whereas the orange-yellow band corresponding to compound II could be eluted with the same solvent. The analysis of compound II is the same as that previously reported."

Announcements

SIR NIGEL POETT has been appointed director of the British Productivity Council on the retirement of Sir Charles Norris.

THE third international Biomagnetic Symposium will be held in the University of Illinois during March 22–23. Further information can be obtained from Prof. M. F. Barnothy, College of Pharmacy, University of Illinois, 833 South Wood Street, Chicago, Illinois.

THE eighteenth technical exhibition of the Oil and Colour Chemists' Association will be held at Alexandra Palace, London, during March 14–18. Further information can be obtained from the General Secretary, Oil and Colour Chemists' Association, Wax Chandlers' Hall, Gresham Street, London, E.C.2.

A CONFERENCE on "Exploiting Instrument Development", arranged by the British Scientific Instrument Research Association, will be held in Eastbourne during March 22–23. Further information can be obtained from Miss A. E. S. Mills, Scientific Instrument Research Association, South Hill, Chislehurst, Kent.

A CONFERENCE, convened by the Organization for Economic Co-operation and Development, on "The Effects of Automation and Technical Change on Labour" will be held in Zurich during February 1–4. Further information can be obtained from the Organization for Economic Co-operation and Development, Château de la Muette, 2 rue André-Pascal, Paris 16.

A SYMPOSIUM on "Planning Mechanical Engineering Departments in Universities", arranged by the Education and Training Group of the Institution of Mechanical Engineers in association with the Royal Institute of British Architects. will be held at the Institution during March 15–16. Further information can be obtained from the Institution of Mechanical Engineers, 1 Birdcage Walk, London, S.W.1.

A DISCUSSION meeting of the Royal Society on "The Structure and Function of Lysozyme" will be held at the Royal Institution on February 3. An ordinary meeting of the Society will follow the discussion. Further information can be obtained from the Executive Secretary, the Royal Society, Burlington House, London, W.1.

24d 13h Mercury 0·7° N. of Mars.

Saturn and Mars become too close to the Sun during the month for favourable observation.

PROGRESS OF INDUSTRIAL RESEARCH IN BRITAIN

*RESEARCH for Industry, 1964**, the report of the Industrial Grants Committee of the Department of Scientific and Industrial Research, covers the first 3 months of 1965 in addition to 1964, and this year comes from the Ministry of Technology. It includes progress reports from thirteen research associations, whose grants came up for renewal in 1964, together with articles by Dr. N. F. Astbury on "Research Associations, Education and Industrial Training", and by S. S. Carlisle on "Automation Research and Development in Research Associations". It also contains the usual directory information on the research associations. The total annual income is now £11·3 million with £2·6 million in grants from the Department of Scientific and Industrial Research, compared with £170,000 and £61,000 respectively in 1927.

At its final meeting the Committee considered an application for a grant from the Machine Tool Industry Research Association, which is growing at a satisfactory rate and doing a most important job. The Committee considers that the Association should be given every possible encouragement and recommends a continuation of the generous terms of this grant.

On grants policy generally, the Committee now favours a revenue grant, usually for 5 years, as a fixed percentage of grant-earning subscriptions over a range of industrial income, and in 1964 seventeen of its eighteen recommendations took this form.

Two ear-marked grants recommended during the year were £34,325 over 3 years, to the Water Research Association to investigate the application of de-salting brackish and sea-waters to British water supply, and up to £39,865, also over 3 years, to enable the Ceramic, Steel Castings and Cast Iron Research Associations to extend their investigations into measuring dust in the working environments of their industries.

A grant announced in 1963, to the Cotton, Silk and Man-made Fibres Research Association, has been increased to £74,600 over 3 years to study new methods of spinning. The British Baking Research Association is also to receive an ear-marked grant of £26,800 towards the cost of a 5-year study of the staling of bread; the Electrical Research Association up to £17,400 for basic research into electrical conduction in dielectrics; and the Timber Research and Development Association half of the £45,000 cost of an operational research study of timber handling over 2·5 years, especially of the feasibility of importing timber into Britain in packages of standard size. A 50 per cent grant not exceeding £38,000 was awarded to the Rubber and Plastics Research Association for an investigation of the possibility of controlling a rubber factory engaged in batch production by a computer, programmed to plan the production in the most efficient way, with regard to utilization of plant and materials. A 75 per cent grant, not exceeding £54,300, is to be awarded to the British Industrial Biological Research Association for research into the injection method of testing food abstracts.

The British Cast Iron Research Association carried out an extensive programme of experimental work to obtain more basic data on cupola melting and to develop improved techniques of melting and metal treatment; much effort was devoted to the development and application of non-destructive testing techniques for iron castings.

One outcome of the Electrical Research Association's work on high-temperature plasmas has been a novel form of plasma furnace which can spheroidize highly refractory particles and may have other important applications. During the past 18 months, the British Hat and Allied Feltmakers' Association has discovered a new method of preparing hatter's fur (this has already reached the stage of production), and also a method of dyeing felt bodies, using the faster classes of dye without recourse to pre-neutralization. In the work undertaken by the Furniture Industries Research Association on comfort of chairs, all existing anthropometric data relating to sitting were surveyed. Furthermore, research is now proceeding on the use of resilient urethane foams for upholstered furniture, on the structural design of chair frames and the joints used in them, and on the avoidance of lacquer waste in spraying furniture.

The inter-firm comparison of the performances of furnaces melting container glasses, which the British Glass Industry Research Association started in 1962, has proved so successful that all British manufacturers are now included, as are more than half the American container glass industry and almost all the Western European firms making glass containers. Considerable contributions have been made towards explaining the basic mechanisms of the corrosion of refractory materials by molten glass and the materials carried in the waste gases, as well as towards the more accurate prediction of the service life of refractories and ways of assessing the effects of changes in refractories on the economics of furnace operation. The Association is also attempting to fill the gap in available knowledge of the process of forming commercial glass by a fundamental investigation, using computer techniques, of the various parameters involved and by direct measurements on the forming machines in the works of members.

The Hosiery and Allied Trades Research Association's basic studies of the factors involved in producing baulked nylon yarns have led to the development and widespread application of two control tests; the crimp rigidity test and the equivalent steam-setting temperature test. A lateral stretch device has been developed for checking the width-wise extension of ladies' hose, as has a quality-control gauge for latch- and bearded-needle flat machines which enables the number of loops in a fixed length of yarn to be determined.

The British Launderers' Research Association has reduced the amount of water required for rinsing without adversely affecting the quality of the work produced. Investigations are proceeding into the application of heat-transfer fluids other than steam to the drying and ironing equipment of laundries, with a view to increasing productivity by the use of higher operating temperatures. Two effective procedures have been developed for disinfecting wool blankets—one involving boiling and the other the use of chemical disinfectants.

The British Leather Manufacturers' Research Association has completed its investigation of the drying rates of different kinds of leather in air at various temperatures, humidities and rates of flow and normal pressure, as well as a 5-year research project on the resistance of leather to heat, moisture and perspiration.

An important achievement has been the introduction of 'Procion' dyes to the leather industry and development of a 'Procion' resist. Addition of benzyl and isopropyl alcohols increased the range of dyes that can be used in spray-dyeing leather and also increased their penetration.

Recent activities of the British Scientific Instrument Research Association in developing industrial measurement techniques have included the development of an emissivity-compensated service pyrometer, which is now undergoing trials in several industries, and a nucleonic gas-flow meter and density gauge. Research is being carried out on techniques of automatic surface inspection, and the development of more efficient detecting screens

for high-energy X-ray fluoroscopy. Work in thin-film technology has been considerably developed and has concentrated on the electrical application of thin films.

The British Steel Castings Research Association is developing special methods of applying materials and has shown that chromite sand is a valuable substitute for zircon sand. Tests have shown that, using this method, austenitic manganese steels can be produced from scrap more economically than by previous methods. Trials are at present proceeding to assess the efficiency of deoxidizers which could lead to the production of superior steels at a lower economic cost.

Research in plant engineering has included the wet reclamation of clay-bonded sand, and investigations of the efficiency and rate of cleaning of steel-castings have shown how shot and other abrasives can be used more efficiently and can provide a method for removing very hard and tenacious cores. In welding technology, the use of a gas shield around a welding arc has proved of great value during the past few years in solving such problems as the welding of thin aluminium alloy sheets, the positional welding of steel and the welding of a whole range of alloys in which metal transfer in the ordinary gas-shielded welding is difficult and erratic. The British Welding Research Association has also overcome difficulties due to resistance in spot-welding by developing a monitoring device which gives a reliable indication of the occurrence of defective welds during the welding operation. Progress already achieved in welding high-tensile steels made it possible for welding to be used in constructing the Forth Bridge, and this is estimated to have cut construction costs by £1 million. A completely new method has been developed for the hydrogen analysis of metals, and methods and equipment developed by the Association to test very large steel plates are now used in every industrial country.

The Welwyn Hall Research Association was formed on October 1, 1964, by the amalgamation of the Whiting and Industrial Powders Research Council and the Chalk, Lime and Industries Research Association. During the past 5 years the Council has advanced over a broad front, rather than in particular fields. The latter Research Association, however, has investigated particularly the problems of the heat balance of shaft lime-kilns and their operation, and this has led to a better understanding of the factors affecting fuel efficiency. An investigation of the factors affecting the quality of calcium silicate bricks has also been undertaken, which has led to the manufacture of stronger bricks with greater dimensional stability.

SPACE AGE SCIENCE AND TECHNOLOGY

APART from what the Earl of Bessborough said in his opening speech, the debate on space age science and technology in the House of Lords on November 3 is of interest mainly for what Lord Shackleton said about Britain's effort in this field and for what Lord Bowden and Lord Snow, who replied to the debate, said about the organization of our research effort and the choice of priorities. The Earl of Bessborough asked some searching questions about the extent of our effort in space research, with which he was dissatisfied. He did not suggest that this effort was necessarily more important than that concerned with other scientific and technological needs, particularly in the less developed countries. The research effort was considerable, but he was concerned that the overall proportion of our research expenditure in the main fields should be right. Lord Shackleton referred to the brilliant report of the Bondi Committee, but said that it could not be published for security reasons. The original estimate of the cost of the European Launcher Development Organization was £70 million, of which our share was 38·8 per cent. When the studies for further programmes were available early next year we should have to consider the estimate very carefully in relation to the technological advantages to be derived from the present and possible future programmes. Concerning satellite communications, he said that the United Kingdom, France and several European countries established in 1963 the European Conference on Satellite Communications and, in the following year, negotiations with the United States, Canada, Australia and Japan led to the drafting of two interim agreements. These covered the establishment of a global satellite system under the Interim Committee on Satellite Communication on which the United States was represented by its Communications Satellite Corporation.

At present there was no alternative to the use of United States launchers and satellites. The *Early Bird* satellite, which is now in regular service and carries part of our transatlantic telephone service, was commissioned before the agreements were signed. It is expected that we will have a global service and that this will render an economic return in due course, but it will take some time for the system to reach a level of development which will be economic. Satellite *Early Bird* was primarily an experiment to determine, first, whether a satellite of this type would provide an acceptable telephone service and, secondly, to gain operating experience. The specification for future satellites which has now been drafted aims at an average life of five years, and it is hoped that, in the future, ten years will be achieved. Although the United Kingdom and the European Launcher Development Organization have the range and supporting facilities of Woomera, there are great advantages in equatorial orbits, and some consideration is being given to the possibility of an alternative launching site near the Equator. Work in Government establishments and in industry on the basic satellite-technology programme has covered design and technological problems relating to satellites, including studies for astronomical satellites and communication satellites and research and development on solar cells, the effect of space environment on electronic components, altitudes sensing, and control systems. Defence Research Establishments had been working on methods of space communication without using man-made satellites. Notable advances in weather forecasting had already been made through the use of space techniques. In the current year the level of expenditure in this field looked like being about £20 million.

In a maiden speech, Lord Ironside referred to the European Space Research Organization Convention, which came into force on March 23, 1964, in which ten countries were now participating, Austria and Norway having dropped out. Much expenditure was at present capital, but the emphasis was slowly shifting to project work. Contributions to the European Space Research Organization, at present something like £7 million, were expected to approach £20 million a year in two or three years' time. Lord Ironside said he thought the return to this country would come first through the return of technologists, after service abroad, and through the placing of contracts in this country by the Organization, which would strengthen United Kingdom industry in space technology and stimulate advances in related technologies, such as telecommunications, vacuum techniques and cryogenics. Lord Bowden's speech was essentially concerned with the organization of civil research and the choice of priorities, and he claimed that the new Council on Science Policy constituted a notable advance. He asked whether the Government proposed to publish Prof.

Flower's survey of the requirements of the universities, and he again expressed his concern that our choice of priorities might be wrong. Lord Sherfield thought manned space research was an example of the fields in which we could not compete. He urged that in the choice of priorities we should build on success and give priority in resources to advanced fields in which we were either still in the lead or among the leaders, instancing nuclear research and technology, fusion research, radiochemistry, radio astronomy and important areas of the biological sciences, as well as some sectors of aviation. He also emphasized the importance of international co-operation, either with single countries as with France in the *Concord* project, or with groups of countries as in the organizations already instanced. He suggested that some countries might tend to support their national programme rather than their share in an international programme to which they were also committed and for this reason he preferred a national effort. He thought our organization of research was soundly based, but regretted that the Industrial Research and Development Authority recommended by the Trend Committee had not been adopted; he believed that the establishment of a Ministry of Technology was a mistake.

Lord Todd also offered a warning against excessive commitment to space research and thought that the advantages coming from technological fall-out were exaggerated. Britain should either support technology with a definite economic aim or support primary scientific research rather than projects in which advantages were reaped from technological fall-out. She must beware of putting too much manpower into scientific research and too little of it into pursuit of technological ends; it was imperative that some hard choices be made which would lead to Britain opting out of some fields of science. He thought we would undoubtedly have to double our present expenditure on scientific research during the next five years, that is to say, there should be a growth rate of about 15 per cent per annum during that period; any cut in this would seriously endanger Britain's position as a leading nation.

EARNINGS OF CHEMISTS

AN article in *Chemistry in Britain* for October 1965 commenting on the remuneration survey, 1965, conducted by the Royal Institute of Chemistry, gives some interesting comparisons of the earnings of chemists with those of other professional people and scientists. Figures for 10 professions in 1964 are given by J. Graham in a series of articles for *The Scotsman*. The average median earnings of chemists in Great Britain between the ages of 30 and 65 are shown by the survey as £2,650 in 1965 compared with £1,600 in 1956. These figures compare with figures for university teachers in 1964 and 1955 of £2,350 and £1,500, respectively. For engineers the corresponding figures are given as £2,200 and £1,210; for graduates in industry £2,575 and £1,570; for doctors (consultants) £4,000 and £3,130, and for general practitioners, £2,765 and £2,160. Figures obtained in a survey by the Institute of Physics in 1964 showed that salaries of its Fellows and Associates had risen by just over 72 per cent in the nine years from 1956, compared with a corresponding rise for chemists over the same period of 66·3 per cent. A typical Fellow of the Institute of Physics can expect to reach a peak of £3,400–£3,500 a year, compared with £3,100–£3,200 for a Fellow of the Royal Institute of Chemistry. Looking at the earnings of chemists in various occupations, private industry no longer leads the field; its highest median salary of £3,100 in the 56–60 age group coming third, behind universities and colleges of advanced technology (£3,460) and £3,150 in the Atomic Energy Authority. Starting salaries in the Scientific Civil Service appear to be outstandingly high, presumably because of more recruitment direct into the Senior Scientific Officer grade, and the subsequent prospects also seem to be better than in most other categories of employment. This closing or narrowing of the gaps between median incomes in industry and those in other occupational categories is particularly interesting in view of current discussions on the possible shortage of scientists. It should be remembered, however, that chemists are not a particularly unified group and are engaged in a very wide range of diverse activities, which sometimes have only a tenuous connexion with their qualifications.

A further article in the November 1965 issue of *Chemistry in Britain* comments that chemistry appears to be about middle of the professions surveyed and that it would appear that the median income levels in all the professions are tending to move closer together: a relatively small change of pace in relation to the general forward movement of incomes could drastically alter the position. Chemists still do considerably better financially in some fields of employment than in others, but such differences also seem to be diminishing. The very low proportion of chemists (0·5 per cent) reporting they were unemployed does not suggest a surplus, and of the 55 out of 10,459 without employment, only 29 had been out of work for more than 3 months, 13 of whom were under 40. While the earnings of older chemists have not increased sufficiently to preserve the differential between them and their younger colleagues, the survey encourages the belief that most chemists whose employers regard them as 'too old at forty' have a good chance of finding one who does not. The survey also shows that any movement of chemists away from industry has been comparatively small, although most of the decline, from 59·6 per cent in 1956 to 55·5 per cent in 1964, occurred in 1962–65.

'O'-LEVEL EXAMINATIONS

FOUR years ago R. W. Crossland and R. Amos presented an analysis of 'O'-level papers of the General Certificate of Education (G.C.E.) in biology of four Boards over the period 1948–59. The analysis was an attempt to quantify the emphasis placed on four main outcomes of biology teaching in the contents of the question papers.

These outcomes are: (1) the acquisition of facts, (2) the interpretation of facts and the drawing of conclusions from experiments, (3) the application of scientific principles to new situations, (4) the designing and planning of experiments.

Late in 1962 a similar analysis of the corresponding papers was made for the period 1960–62 and more recently the analysis was brought up to date by including the papers for 1963 and 1964*. The results of the three analyses are here shown separately, and, for comparison, the corresponding figures for the other science subjects are also shown (Table 1).

The analyses show the relative proportions of acquisition of facts and scientific method for the various sciences at 'O' level. Biology papers devote about 90 per cent of questions to facts. There are those who hold that one needs to know a good many biological facts before one can do much reasoning. The authors suggest that the Nuffield Foundation Teaching Project and similar pro-

jects in Britain and the United States will develop new teaching techniques which will also show how to give young pupils an understanding of the nature of the scientific process.

To-day the goal of mastering the factual content of a subject is not sufficient; there are other goals and needs at all levels of learning. The teaching of facts and method may go hand in hand. It is how the facts are learned and organized that makes a difference. Science is most effectively taught and learned when both pupils and teacher practise scientific investigation—when they devise experiments to solve problems and improvise simple apparatus for carrying them out.

One would expect general science, chemistry and physics papers to have smaller percentages of factual questions, because it has long been the standard practice in the teaching of physical sciences to apply scientific principles in numerical problems. About 20 per cent of the general science and chemistry papers and 40 per cent in physics are devoted to 'Application'. But, in general, these problems are formal and stereotyped and amount to little more than a memory test. There is no real, new scientific problem to solve.

About 20 per cent of chemistry papers and slightly less percentages in the other scientific subjects deal with experimental work. Here again, this is rarely more than memory work, dealing with hoary experiments and demonstrations which have been thoroughly rehearsed. Rarely is a candidate expected to show imagination and ingenuity in devising experiments to test hypotheses which are new to him.

In their article, Crossland and Amos provide further evidence to show that scientific method is virtually ignored in 'O'-level science courses. They discuss the implication of this deficiency for the education of all pupils and make suggestions for a shift in emphasis from mere memory work towards some appreciation of scientific methods in 'O'-level examinations.

The syllabuses in biology, general science, chemistry and physics of the nine General Certificate of Education Examining Boards were also examined. Apart from one Board, the Oxford and Cambridge, references to scientific method in biology, chemistry and physics are limited. In biology they are confined to a training in observation and recording; "Biological knowledge should be based on observation of living plants and animals both in the laboratory and out of doors" is typical. Practical work in physical sciences is meant to give a training in skills and techniques, and in carrying out directions. In general science there are clearer signs that scientific method should be taught; for example, in the Cambridge syllabus we read " . . . the student should be led to some appreciation of scientific principles and methods by which they have been established". But the one Board which comes nearest to the treatment of scientific method is the Oxford and Cambridge. In its biology syllabus it states: (1) " . . . (candidates) expected to draw conclusions from simple experiments which they perform". (2) " . . . to understand the necessity for control experiments". (3) " . . . questions . . . which test powers of observation and reasoning of candidates". The general conclusion to be drawn from a study of the syllabuses is that only a limited amount of scientific method is expected at 'O'-level.

FUEL UTILIZATION

FUEL utilization is often regarded as the Cinderella of industry. Industries such as aircraft, motor cars, electronics and computers regard the designers of combustion chambers, boilers and furnaces as belonging to a comparatively primitive and unenterprising sector of industry. Such a view is only justified to the extent that the very small profit margins of old-established industries, which were in existence at the very beginning of the industrial revolution, allow only a small fraction of their annual turnover to be spent on research and development. In the case of units such as power station boilers or blast furnaces, each of which costs hundreds of thousands, if not millions, of pounds, the difficulties of developing a radically new and better design are immense, and unless there is a co-ordinating national development programme it is impossible to undertake the development of a greatly improved new type of appliance. Work with small pilot plant for such a new idea costs tens of thousands of pounds, and work with large pilot plant, which is essential to give answers to the economic questions of capital cost, reliability and required quality of constructional materials, costs in the range of hundreds of thousands of pounds.

It is, therefore, particularly timely and of national importance that the Institute of Fuel should have devoted the whole of a four-day conference to fuel research and development*.

The first paper in the conference was a directory of organizations carrying out research and development. This covers industrial firms and research organizations of the fuel industries, and ranges from small individual burner-makers up to organizations like Imperial Chemical Industries, Ltd., and Shell. Strangely enough, it does not, however, include any work done by universities and technical colleges. a number of which are doing valuable work at the small pilot plant and bench scale stages of applied research. The authors of the directory conclude that about 2,900 graduates and 5,000 non-graduates are working in the organizations covered by their survey and that the annual expenditure on fuel research and development excluding nuclear energy is just under £20 million. If we take it that the national annual fuel bill is of the order of £2,000 million, this comes out at 1 per cent, a very much lower figure than would be found in the more rapidly changing industries.

The first main session of the conference dealt with the organization of a research department, and the papers covered a number of interesting points, including French,

* Institute of Fuel. *Proceedings at the Conference on Fuel Research and Development held at Eastbourne, 4th to 8th October, 1965.* Vol. 1: Papers. Pp. 294. *Conference Handbook.* Pp. 14. (London: The Institute of Fuel, 1965.)

American and Hungarian organizations. My criticism of this section would be that it does not give sufficient emphasis to the long-term practical objects of fuel research and development, namely, how to obtain the desired output of the product with improved quality and regularity and reduced capital and running costs.

The next three papers dealt with the approach to research and its assessment and communication. The special problem of fuel research is that it does not attempt to attract the most original-minded youngsters in the schools, but its advantage is that people are prepared to discuss comparatively openly the new ideas which arise in these fields. The paper by the National Research and Development Council is very authoritative, as they have been working for many years on the best way of assessing new projects. Their particular fuel interests at the moment are connected with an automatic oil drill rig, fuel cells, high temperature combustion and new materials. Most new developments in fuel technology pose new problems for materials either in terms of chemical resistance or strength at high temperatures. This is well illustrated by the fact that Lord Fisher wrote to Charles Parsons in 1909 suggesting that a Parsons turbine should be operated on combustion gases, whereas it was not for another 30 years that steels were available to provide the necessary strength under the required temperature conditions.

The remaining sessions of the conference follow very logically the stages of development; the bench stage is illustrated by studies on pulverized coal, shock tubes and electrically augmented flames. These last two have not yet found any commercial application, but have interesting possible applications in the field of high-temperature endothermic reactions or the production of reaction intermediates. The small and large pilot plant work is illustrated by work on flow patterns and a general account of the work of the International Flame Research Foundation on pulverized coal flames. The Ijmuiden experimental furnace of the International Flame Research Foundation can be regarded as a large pilot plant for the study of new kinds of flames for boilers and furnaces. Apart from this there is a great dearth of work with large pilot plant in the fuel field which makes it very difficult for any radically new process to be developed. This is because the cost of building a large pilot plant is at least one-tenth of the cost of the final equipment.

The final section dealing with applications is particularly satisfactory since it contains two examples of the successful application of two quite new processes, namely: (1) the reforming of naphtha to make town gas; (2) the development of the fuel for the advanced gas-cooled nuclear reactor together with some work on minor changes such as the injection of fuel into the tuyères of a blast furnace and the high intensity gas burner.

The discussion at the conference was very lively and there is no doubt that the conference provided a valuable stimulus to this very important branch of applied science.

M. W. Thring

ATMOSPHERIC CLEAR AIR TURBULENCE

By Dr. RICHARD L. MOORE and Prof. T. N. KRISHNAMURTI*
Douglas Aircraft Company, Inc., Long Beach, California

THE purpose of this article is to report on a matter of considerable interest to aircraft operations. A new approach has been made to the problem of clear air turbulence from the point of view that energy is provided by the transfer from large (or synoptic) scale flows toward the smaller-scale flow in the gravity wave spectra. Although the exact mechanics of such transfer have not been computed, the synoptic conditions favourable for the rapid transfer of energy have been predicted from inviscid flow theory.

Synoptic evidence given by previous investigators, including Endlich[1], Reiter[2], and George[3], from examination of weather maps has confirmed the suggestion that there are certain well-recognized, large-scale patterns associated with the major outbreaks of clear air turbulence.

Endlich[1] and Reiter[2] noted that large vertical shears with strong backing of wind with height are frequently found in regions of clear air turbulence. The synoptic maps show a westerly polar jet stream beneath a strong south-westerly sub-tropical jet stream. How, precisely, an instability arises in these large-scale flow configurations is not understood, and hence the precise modes of energy transfer from the larger to the smaller scales are as yet little known.

In most investigations of clear air turbulence the emphasis has been on the use of local values of parameters such as the Richardson number (Endlich[1]) or the Scorer parameter (Reiter[2]). It is a basic premise of this article that these, or any other, parameters are only important in the region where turbulence is created, and in that region are only important at the time before inviscid flow breaks down into turbulence. Thus, once a turbulent eddy is excited it may be too late to look at these parameters since the flow field will be changed because of the onset of turbulence.

In our investigations the object is to explain clear air turbulence in terms of the following hypotheses: (*a*) Shear is generated rapidly in some region of the atmosphere to be called the source region. (*b*) The shear reaches a critical value and the flow field becomes turbulent. (*c*) The turbulent flow field is carried away from the source region and gradually decays.

The shear is measured in terms of the vorticity vector, $\mathbf{W}$, which is expanded in a Taylor's series, assuming the convection and diffusion of vorticity are small:

$$\mathbf{W}(t) = \mathbf{W}(0) + \left(\frac{\partial \mathbf{W}}{\partial t}\right)_0 t + \left(\frac{\partial^2 \mathbf{W}}{\partial t^2}\right)_0 \frac{t^2}{2} + \ldots \qquad (1)$$

In order to test the importance of effects which are non-linear with time, we have examined, on weather maps, values of $\partial^2\mathbf{W}/\partial t^2$ calculated from a formula derived from the following theoretical approach (details of which have been over-simplified for the purpose of discussion).

The equation of motion in a fixed frame of reference for an inviscid fluid is:

$$\frac{d\mathbf{V}}{dt} = -\frac{1}{\rho}\nabla p - g \qquad (2)$$

p is the pressure, ρ is the density; $-g$ is the gravitational force. $d\mathbf{V}/dt$ is the acceleration. The operation of $\frac{\partial}{\partial t}(\nabla \times)$ on equation (2) yields:

$$\frac{\partial}{\partial t}\left[\nabla \times \frac{d\mathbf{V}}{dt}\right] = -\frac{\partial}{\partial t}\left[R\nabla T \times \nabla \ln p\right] \simeq R\nabla T \times \nabla(\nabla.\mathbf{V}) \qquad (3)$$

The last step follows from the equation of continuity and the neglect of $\partial T/\partial t$. (*Note.* A more rigorous derivation by Moore[4], which is too long for this article, has shown that if diabatic heating is neglected, the relation is:

$$\frac{\partial^2 \mathbf{W}}{\partial t^2} + \frac{\partial}{\partial t}\left[(\mathbf{V}.\nabla)\mathbf{W} - (\mathbf{W}.\nabla)\mathbf{V} + \mathbf{W}(\nabla.\mathbf{V})\right] = \nabla\gamma RT \times \nabla(\nabla.\mathbf{V}) + \nabla RT \times \nabla(\mathbf{V}.\nabla \ln p) + \nabla\{(\gamma-1)\,RT\,\nabla.\mathbf{V} + \mathbf{V}.\nabla\,RT\} \times \nabla \ln p$$

* University of California, Los Angeles, California.

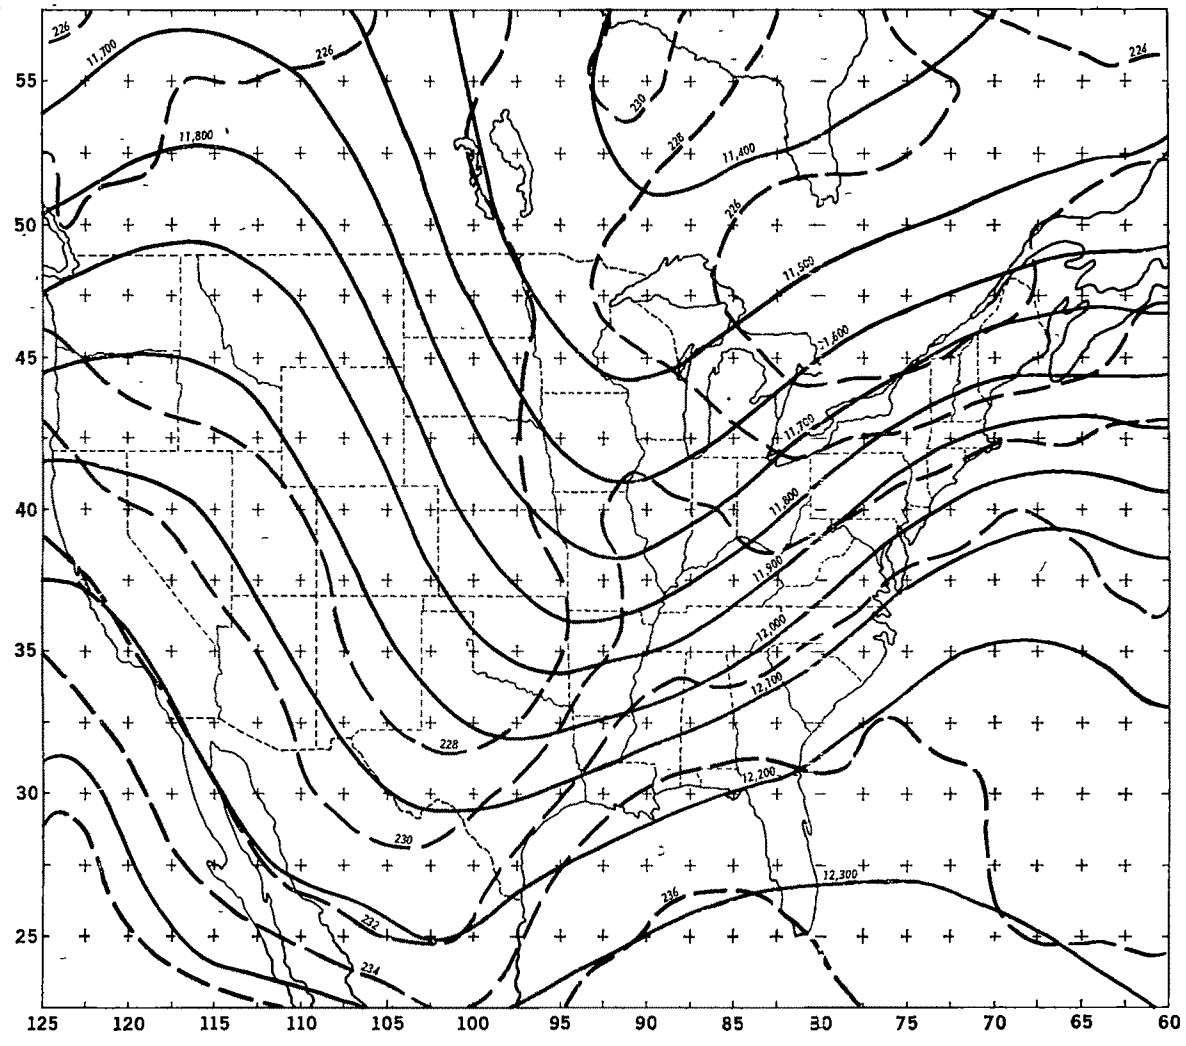

Fig. 1. High-altitude pressure and temperature field, April 13, 1962, 00Z. Solid lines are contours in metres of the 200-mbar pressure surface. Dashed lines are the isotherms at the 300-mbar level (in °K)

If the velocity normal to a surface of constant pressure is small, the 'vertical' component of the right-hand side of this equation is the component of $\nabla (\gamma RT) \times \nabla(\nabla.\mathbf{V})$ normal to the constant pressure surface.) On neglecting the partial derivative with respect to time of the convective terms involving the vorticity (the second term on the left side of the equation in the foregoing *Note*), the left side of equation (3) becomes $\partial^2 W/\partial t^2$. Thus the first non-linear term in equation (1) is proportional to $\nabla T \times \nabla (\nabla.\mathbf{V})$.

Application to a synoptic situation. As a test of the foregoing hypotheses (*a*) and (*b*), the vertical component of $\nabla T \times \nabla(\nabla.\mathbf{V})$ has been computed and plotted on a series of weather maps which correspond to the well-documented case study published by Reiter[2]. The values for the parameter already mentioned have been compared with the distribution of clear air turbulence also reported by Reiter.

We used the following method to compute the vertical component of $\nabla T \times \nabla(\nabla.\mathbf{V})$ in equation (3). It is easily

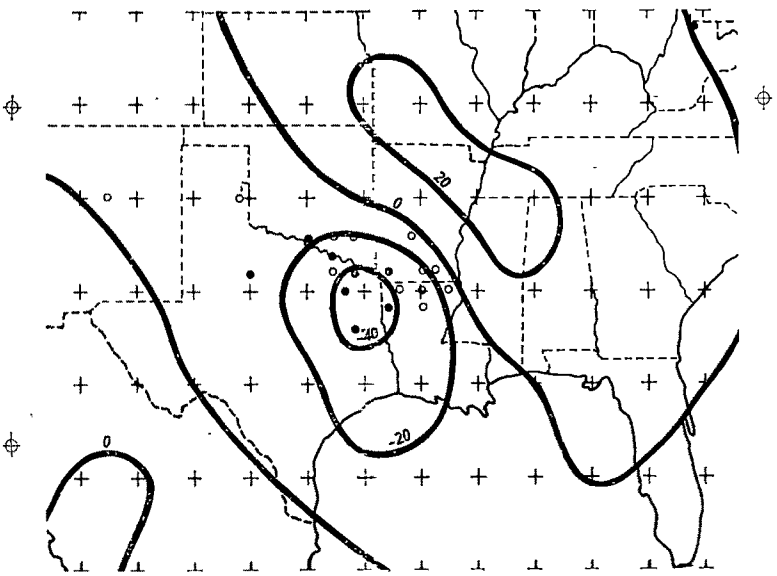

Fig. 2. Curves of constant value of the Jacobian of temperature and divergence of the velocity on the 300-mbar surface. Values in units of 10^{-17} deg sec^{-1} m^{-2}. Solid circles mark location of severe clear air turbulence. Open circles correspond to moderate clear air turbulence. Clear air turbulence data due to Reiter (ref. 2)

shown that $\nabla T \times \nabla(\nabla . \mathbf{V}).k$ is identical with the Jacobian of T and $\nabla . \mathbf{V}$ which is easily computed. $\nabla . \mathbf{V}$ on a constant pressure surface can be shown to equal

$$-\frac{1}{\gamma p}\frac{dp}{dt}$$

which is evaluated from the well-known quasi-geographic dynamical equation (see Thompson, ref. 5).

As an indication of the validity of the theory, Fig. 1 shows the temperature field at 300 mbars and flow field at 200 mbar for 00Z on April 13, 1962. Fig. 2 shows the vertical component of $\nabla T \times \nabla(\nabla . \mathbf{V})$ over the central part of the United States.

The open circles represent moderate turbulence, and the solid circles represent severe turbulence reported by pilots within 6 h of the time of observation. It is obvious that in this case the shear has been generated rapidly in a source region located near the north-east border of Texas, and that the flow field has also become turbulent, thus agreeing with our hypotheses (*a*) and (*b*). The increase in the number of the reported cases of moderate turbulence in the down-wind direction does not disagree with the hypothesis that the turbulence is carried away by the winds from the source region and gradually decays. A more complete analysis of this situation is in the process of preparation.

George[3] has previously pointed out the importance of the temperature gradient from an empirical analysis of synaptic situations associated with clear air turbulence. Similarly, Reiter[2] pointed out the importance of the convergence or divergence of the flow field; Stinson[6] has recently made a qualitative investigation of this factor. The probability of the validity of the theory of this note appears to be enhanced because it combines both the temperature gradient and the divergence of the velocity in one numerical factor, and provides a theoretical justification of the foregoing experimental deductions.

We thank Mr. J. J. George for his advice in this work, which was supported by the Douglas Aircraft Company Independent Research and Development Program.

EFFECT OF CARBON DIOXIDE ON THE SHATTERING OF FREEZING WATER DROPS

By J. E. DYE and Prof. P. V. HOBBS
Department of Atmospheric Sciences, University of Washington, Seattle

THE production of numerous ice particles by the shattering and splintering of freezing drops has been widely accepted as an important process which occurs under natural conditions in supercooled clouds. Braham[1], for example, has invoked this phenomenon in order to explain the high concentration of ice particles found in summer cumulus clouds over Missouri, while Latham and Mason[2] have proposed a theory of thunderstorm electrification which is based on the charge separation that accompanies the production of ice splinters.

Direct evidence for the shattering and splintering of freezing drops rests on laboratory experiments made by a number of workers (Langham and Mason[3], Mason and Maybank[4], and Stott and Hutchinson[5]). The most complete investigation of the effect is probably that of Mason and Maybank[4], and this work appears to show quite clearly that when the temperature at which a drop is nucleated falls below about −4° C, a sharp decrease occurs both in the probability of shattering and in the number of ice splinters which are thrown off from the freezing drop. For example, Mason and Maybank found that for drops of 1 mm radius nucleated at −1° C, 47 per cent shattered and, on average, 54 splinters were produced per drop; however, with a nucleation temperature of −7° C, only 6 per cent of the drop shattered and the average number of splinters fell to about 13. For nucleation temperatures below about −9° C, not one drop was observed to shatter and the average number of splinters was about 4.

The method normally used to nucleate supercooled drops at temperatures above −4° C is to drop a small piece of solid carbon dioxide into the cold chamber in which the drop is situated. The passage of the cold carbon dioxide through the air results in the production of numerous small ice crystals, some of which collide with the surface of the drop and initiate freezing. Of course, carbon dioxide may be used to cause nucleation below −4° C, and very often is, but nucleation at these lower temperatures may also be achieved using an artificial ice nucleus such as silver iodide. In the experiments of Stott and Hutchinson[5], carbon dioxide was used exclusively. Langham and Mason do not mention the method used for nucleating the drops, but it is likely that carbon dioxide was used on occasions; Mason and Maybank[4] used both carbon dioxide and silver iodide, but for nucleation above −4° C only carbon dioxide could have been used. During the course of an investigation in this laboratory into the crystallographic structure of freezing drops, it became obvious that the presence of carbon dioxide gas could have a profound effect on the manner in which a drop froze. Accordingly, experimental work was undertaken to determine the effect of carbon dioxide on the shattering of freezing drops.

The experimental arrangement was as shown in Fig. 1. By pumping methanol, previously cooled in a liquid nitrogen bath, at various rates through the hollow walls of a small chamber (approximately a cube of side 2 in.), the interior of the chamber could readily be maintained at any temperature from 0° to −40° C. Changes in the temperature of a drop during the cooling and freezing process were measured continuously by suspending the drop on the tip of a thermocouple 0·005 in. in diameter which was connected through an amplifier to a chart recorder. An additional thermocouple was placed in the chamber and close to the drop in order to record the temperature of the environment. Double glass windows in two of the sides of the chamber allowed for illumination and visual observation of the drop. Ice crystals, needed to nucleate the supercooled drops, were introduced without the use of solid carbon dioxide by momentarily lowering into the chamber a small metal rod cooled by liquid nitrogen.

In a series of preliminary experiments a number of drops were frozen in the chamber in an environment of ordinary air. The drops varied in diameter from 0·6 to 1·6 mm and were nucleated with ice crystals introduced

into the chamber either by using the metal rod already described or by placing a small amount of liquid nitrogen into the chamber. The rates of cooling used varied from 5° C/min to 160° C/min and the nucleation temperatures ranged from 0° to −20° C. In all, 150 drops were frozen in this manner, but not one drop was observed to shatter. However, about 50 per cent of the drops developed small spikes (approximately 0·2 mm in length) during freezing, and about one drop in every ten developed a long spike (approximately 1 mm in length). Following these experiments, a number of drops were nucleated with ice crystals produced by dropping a small piece of solid carbon dioxide into the chamber. Under these conditions about one-third of the drops shattered. These experiments suggested quite strongly that the shattering of the freezing drops was associated with the presence of carbon dioxide in the cooling chamber.

In order to investigate the effect of carbon dioxide on the shattering of freezing drops in a more quantitative manner, an addition was made to the experimental apparatus which allowed definite concentrations of carbon dioxide to be introduced into the chamber. This addition consisted of two flowmeters and associated cooling coils (Fig. 1). Into one of the flowmeters pure air was introduced at a known rate and into the other pure carbon dioxide gas; after passing through the cooling coils this mixture was allowed to enter the cooling chamber. With this experimental arrangement the following procedure was adopted. A drop of singly distilled water, usually of about 1 mm diameter, would be suspended on the top of the thermocouple and then lowered into the upper part of the chamber, where the temperature was about 2° C. A known mixture of carbon dioxide and air was passed continuously into the chamber at a constant rate of 200 ml./min independent of the concentration of carbon dioxide; shortly afterwards ice crystals would be produced in the lower part of the chamber by introducing the metal rod cooled by liquid nitrogen. After the drop had been exposed to the air–carbon dioxide mixture for 2 min at 2° C, it would be lowered quickly to the −10° C level in the chamber and its mode of freezing observed through a telescope. Prior to changing the concentration of carbon dioxide in the mixture, the chamber would be flushed thoroughly with clear air. The foregoing procedure was repeated for twelve different concentrations of carbon dioxide, and at each concentration ten drops were frozen. The temperatures at which the drops nucleated in these experiments varied from 0° to −5° C.

The manner of freezing, and the probability of a drop shattering, were found to change markedly as the concentration of carbon dioxide to which the liquid drop had been exposed was increased. For very low concentrations of carbon dioxide (less than 1 per cent) only minor bulges and small spikes formed, and some small cracks were observed in the surfaces of the frozen drops. When the concentration of carbon dioxide in the mixture reached about 25 per cent, however, long ice spikes of up to 2 mm in length were forced out from the freezing drop and violent shattering and cracking occurred. As the concentration of carbon dioxide was increased above 75 per cent huge protuberances formed containing large quantities of gas; these protuberances usually ruptured at their ends as the gas was forced out, and the drop sometimes shattered completely.

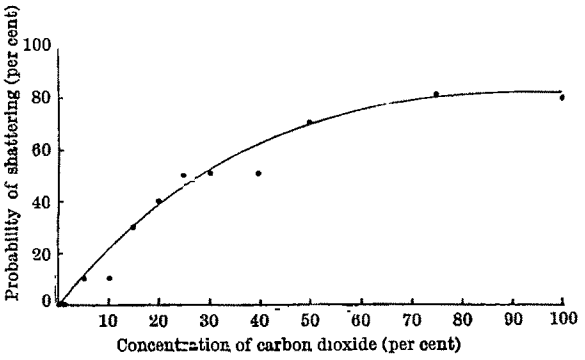

Fig. 2. The probability of a drop shattering on freezing as a function of the concentration of carbon dioxide in the environmental gas (for details see text)

The results of these experiments are shown in a quantitative manner in Fig. 2, where the probability of a drop shattering is plotted against the concentration of carbon dioxide gas in the mixture to which the liquid drop is exposed at 2° C. These results show quite clearly that the probability of shattering increases rapidly as the concentration of carbon dioxide in the mixture increases. For concentrations of carbon dioxide less than 1 per cent the probability of shattering is effectively zero. In this figure the term 'shattering' includes the complete disintegration of a drop or a spike, the breaking off of part of a drop, or noticeable fragmentation of the surface of the ice when a gas bubble emerges from the end of a protuberance.

In order to determine whether, even after being subjected to relatively high concentrations of carbon dioxide gas, drops shatter only when nucleated above −5° C, twenty liquid drops were subjected to an air–carbon dioxide mixture containing 25 per cent carbon dioxide, and these drops were then nucleated at approximately −12° C in the manner already described. Six of the twenty drops shattered—four disrupting completely and two forming spikes which later shattered. Although this gives a probability of 30 per cent, as compared with a probability of 50 per cent for drops subjected to 25 per cent concentration of carbon dioxide and nucleated above −5° C, it demonstrates that, provided a liquid drop has been situated in an environment containing a relatively high concentration of carbon dioxide, it may shatter during freezing even though it is nucleated below −5° C. Indeed, drops subjected to high concentrations of carbon dioxide have been observed to shatter when nucleated at temperatures as low as −19° C.

The effect of carbon dioxide on the shattering of freezing drops may be understood in general terms as follows. Carbon dioxide is approximately one hundred times more soluble in water than is nitrogen and nearly fifty times more soluble in water than is oxygen. The solubility of carbon dioxide in ice, on the other hand, is very small compared with that in liquid water. Therefore, as a drop freezes radially inwards, the carbon dioxide in the liquid water will be forced out as gas bubbles, and this will result in the build-up of large stresses in

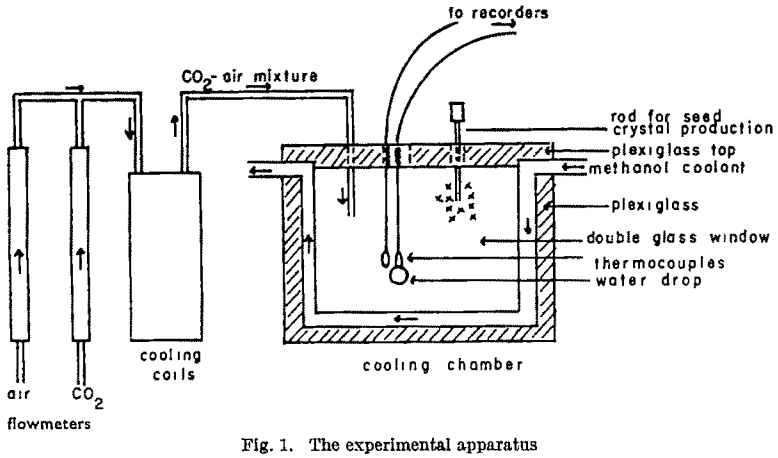

Fig. 1. The experimental apparatus

the surrounding ice shell. Under these stresses water may be pushed out from the interior of the drop to form spikes and bulges on the surface of the sphere, and, if this is not sufficient to accommodate the increasing pressure in the interior, complete shattering of the drop will occur. Since the concentration of carbon dioxide in liquid water increases linearly with the partial pressure of carbon dioxide in the environmental gas, the increase in the probability of shattering with increasing concentration of carbon dioxide (Fig. 2) is readily understood. The expansion of the water as it freezes in the interior of a drop will also contribute to the tensions in the ice shell, but our experiments show that this effect alone is insufficient to cause shattering.

In the light of these results we suggest that the shattering of freezing drops observed in the laboratory by previous investigators was in all cases probably due to the presence of carbon dioxide in solution in the liquid water. Moreover, we would ascribe the apparent effect of nucleation temperature on shattering, observed by Mason and Maybank[4], to the use of carbon dioxide for seeding at temperatures above −4° C. From the appearance of the long spike shown in Fig. 2 of Mason and Maybank's paper, we would judge that the liquid drop had been exposed to an environmental gas containing about 25 per cent carbon dioxide gas. If this were the case, according to our Fig. 2 the probability of shattering would be approximately 50 per cent and, for nucleation temperatures above −4° C, this is in good agreement with the statistics for shattering given by Mason and Maybank.

It follows also from our results that under natural conditions in the atmosphere, where the concentration of carbon dioxide is always less than about 0·06 per cent, the shattering of freezing drops probably never occurs. However, the introduction of sufficient quantities of carbon dioxide gas into a natural cloud could give rise to the shattering of droplets during the freezing process. In fact, we would suggest that the seeding of supercooled clouds with silver iodide might be more effective if large quantities of carbon dioxide gas were introduced into the cloud just prior to seeding.

It should be noted that the results reported in this article refer only to the shattering of freezing drops and not to the production of splinters. However, shattering and splinter production are intimately connected, for both phenomena derive from the build-up of stresses in the freezing drop. It therefore seems likely that the number of splinters thrown off from a freezing drop will increase as the concentration of carbon dioxide in the liquid drop rises. Measurements of the effect of carbon dioxide on splinter production are now being undertaken and the results will be published in due course.

A COMPARISON OF TOTAL MAGNETIC FORCE SECTIONS ACROSS NORTHERN CALIFORNIA AND SOUTHERN NEW ZEALAND

By T. HATHERTON

Geophysical Survey, Geophysics Division, Department of Scientific and Industrial Research, Wellington, New Zealand

GRANTZ and Zietz[1] have compared magnetic profiles across "belts of moderately deformed sedimentary rocks" in Alaska and California. These profiles record broad highs in total magnetic intensity over the Jurassic and Cretaceous marine sedimentary rocks underlying the Cook Inlet and Copper River lowlands in Alaska, and over similar rocks underlying the northern and central Great Valley, California. These highs are parallel to the major geological features in each area, and are absent over parallel belts of more severely deformed sedimentary rocks of similar age which occur in the bordering Chugach Mountains and Alaska Range in Alaska, and in the Coast Ranges in California.

Similar geological situations exist in New Zealand and California. In Southland, New Zealand (Fig. 1), the old land mass of Fiordland is bordered on the east by a syncline of gently deformed marine and freshwater sediments (Hokonui facies) of great thickness (~ 50,000 ft., according to Wellman[2]). This syncline is known as the New Zealand marginal syncline[3]. Farther east still are the severely deformed parallel greywackes (Alpine facies) and schists that were deposited in the New Zealand geosyncline. Between the marginal syncline and the New Zealand geosyncline are found ultramafic and ultrabasic rocks.

Fig. 2 compares the aeromagnetic total force profiles across the Sacramento Valley and Coast Ranges in California with the seaborne total force profiles round the south-east coast of the South Island, New Zealand. Because the rock sequences are from west to east in New Zealand and east to west in California, the New Zealand profile has been reversed for easier comparison.

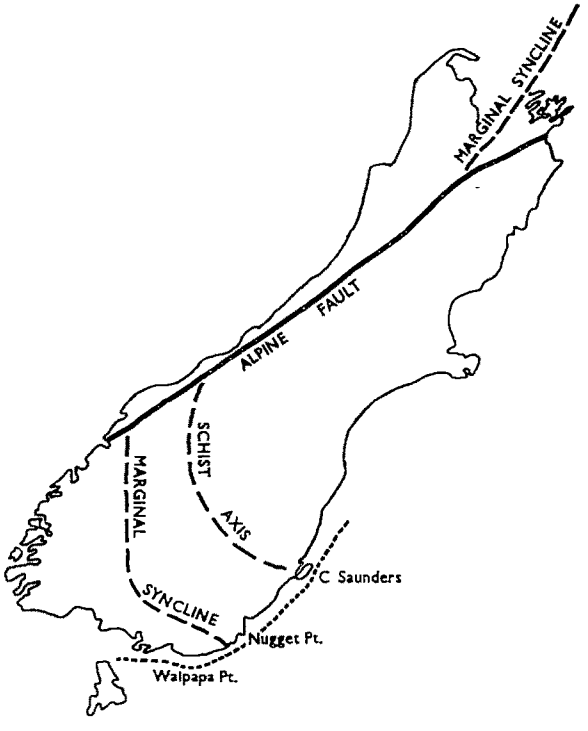

Fig. 1. South Island of New Zealand, showing principal structural features, and track of magnetic observations (dotted line)

The following parallels can be drawn, going from right to left in Fig. 2.

(1) At the western end of the New Zealand profile the many narrow peaks are due to the underlying pyroclastics, pillow lavas and shallow intrusives of gabbro, diorite and biotite granite of the Longwood complex. The comparable eastern part of the profile in California was not recorded by Grantz and Zietz, but they state that "available magnetic data over the Jurassic slate and greenstone belt of the Sierra Nevada, which borders the Great Valley on the east, record so many magnetic features of shallow origin that it is difficult to determine whether or not broad magnetic highs occur there".

(2) Between Waipapa Point and Nugget Point on the New Zealand profile is a broader anomaly 35 miles in width and of amplitude varying from 500 to 1,000 gammas. The anomaly over the northern and central Great Valley is about "30 miles wide and ranges in amplitude from a few hundred to more than 1,000 gammas"[1]. The crests of the magnetic highs lie respectively a few miles west and a few miles east of the thickest parts of the sedimentary prisms in Southland and the Great Valley.

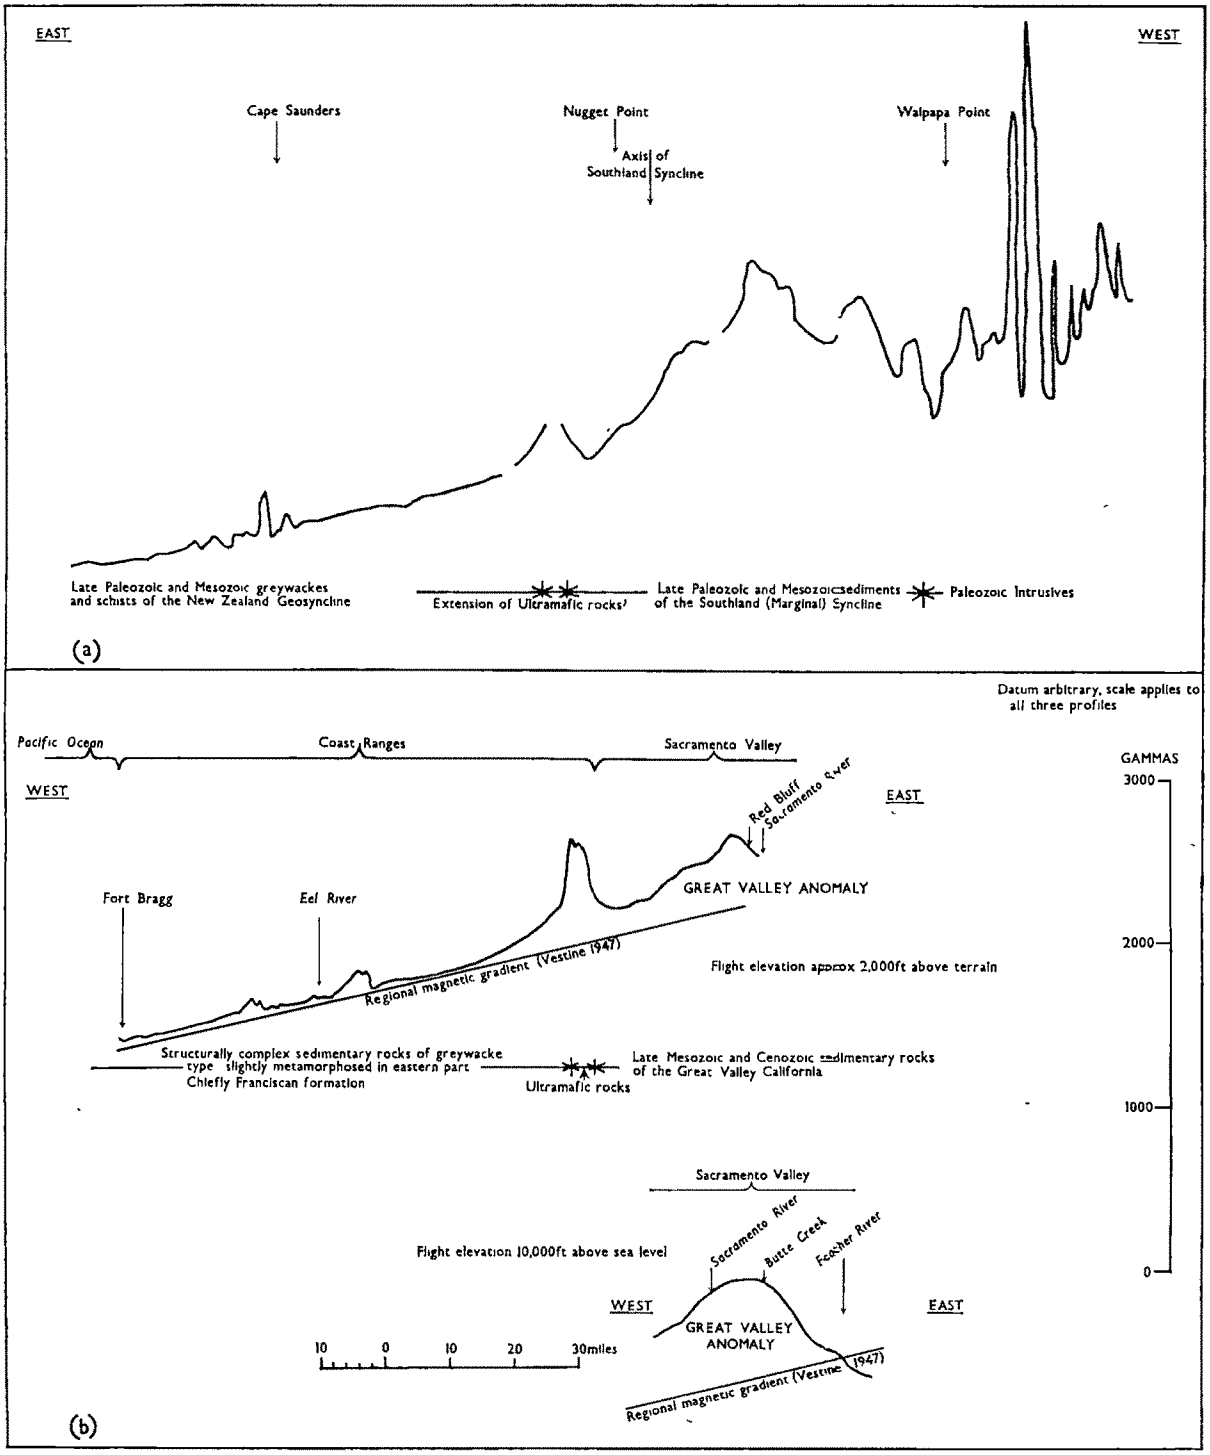

Fig. 2. (*a*) Total force magnetic profile around south-east coast of South Island, New Zealand. Observations at sea-level (*b*) Total force magnetic profiles across northern California. Observations at elevations given in Figure. (After Grantz and Zietz (ref. 1))

Pure C... SCIENCE ...

That is, in both cases, the highs are on the continental sides of the marginal synclines.

(3) Between the overturned north-eastern flank of the New Zealand marginal syncline and the schists to the north-east is a single narrow anomaly of about 300–400 gammas (though reaching 1,200 gammas elsewhere). This can be traced north-west along the junction of the marginal and geosynclinal facies until it joins exposures of volcanic and ultramafic rocks 80 miles away at Mossburn[4]. At a similar position in the Californian sequence a single 600-gammas peak coincides with exposed ultramafic rocks.

(4) Over the New Zealand geosyncline magnetic anomalies are small except where late Tertiary volcanics (Cape Saunders–Taiaroa Head) are exposed. Over the Coast Ranges of California there are minor anomalies which are due to basic volcanics or ultramafics.

The most interesting sections of these profiles are the broad magnetic highs over the marginal synclines. The Bouguer gravity anomaly associated with the magnetic high in the Great Valley of California is about 20–40 milligals. There is no significant gravity anomaly associated with the magnetic anomaly in Southland, New Zealand[4]. Thus in the latter case it has been assumed that the density of the disturbing magnetic rock is about 2·65 g/cm³ which is the density of the Late-Palaeozoic to Mesozoic sediments of the syncline. Permian sediments of this density and with magnetic susceptibilities of up to 4,000 × 10^{-6} c.g.s. units occur within the area of the magnetic high, but it is unlikely that these are extensive enough to cause the major high, though they may cause local noise[4]. Of igneous rocks, only serpentine and perhaps andesite appear to have the relatively high susceptibility and low density to explain the high magnetic anomaly and lack of gravity anomaly. The Southland syncline is separated from its supposed extension, the Nelson syncline, by the transcurrent Alpine Fault. Hatherton[5] has suggested that the magnetic and gravity anomalies in the Nelson–Cook Strait region can be best explained by a dunite-serpentine system. Such a system generally shows an inverse relationship between density and magnetic susceptibility[5].

As Grantz and Zietz pointed out after studying the California and Alaska profiles, "there may be a causal relationship between the existence of the rocks that produce the broad magnetic highs and the structure and lithology of the sedimentary prisms that overlie them". The addition of the New Zealand results increases the probability that the broad magnetic highs resulting from apparently deep-seated igneous rocks are a generic characteristic of the stable synclines adjoining geosynclines.

I thank Prof. George A. Thompson of Stanford University for bringing the results of Grantz and Zietz to my notice.

DETECTION OF HYDROGEN EMISSION LINES $n_{159} \rightarrow n_{158}$ AND $n_{157} \rightarrow n_{156}$ IN GALACTIC H II REGIONS

By Prof. A. E. LILLEY, Prof. D. H. MENZEL, H. PENFIELD and B. ZUCKERMAN
Harvard College Observatory, Cambridge, Massachusetts

In 1959, Kardashev[1] predicted that spectral lines of excited hydrogen of the $n \rightarrow n - 1$ type could be observed in galactic H II regions. In particular, he showed that the most readily observable lines should appear in H II regions having a high continuum temperature and that lines of the type $n \rightarrow n - 2$, $n \rightarrow n - 3$, etc., should be less intense than those of type $n \rightarrow n - 1$.

The detection of lines of this type was first announced by two groups of Russian observers[2,3], who found the line $n_{105} \rightarrow n_{104}$ (ν = 5,762·9 Mc/s) in *M*17 and the Orion Nebula, and the line $n_{91} \rightarrow n_{90}$ (ν = 8,872·6 Mc/s) in *M*17. More recently, Hoglund and Mezger[4] observed the line $n_{110} \rightarrow n_{109}$ (ν = 5,008·9 Mc/s) in a number of galactic H II regions.

We have detected two new hydrogen lines corresponding to the transitions $n_{159} \rightarrow n_{158}$ (1,651·544 Mc/s) and $n_{157} \rightarrow n_{156}$ (1,715·676 Mc/s) in two galactic sources, *M*17 and *W*51. Local radio interference prevented a search for the intermediate transition $n_{158} \rightarrow n_{157}$ (1,683·203 Mc/s). Our data were obtained with the Harvard 60-ft. telescope equipped with a 10-channel cavity maser radiometer with a resolution of 80 kc/s. The antenna half-power beam-width was 52 min of arc and its aperture efficiency was 0·38 at the wave-length of operation. The total noise temperature of the system was approximately 100° K. Figs. 1–4 show the profiles obtained with this system, and Table 1 summarizes our results.

To interpret their observational results, Hoglund and Mezger assumed a Gaussian line shape and a Maxwellian distribution of electron velocities at temperature T_e. The total energy observed in a line is then:

$$\Delta\nu_L T_L = 1{\cdot}67 \times 10^6 T_e^{-3/2} E \text{ deg/sec} \qquad (1)$$

where $\Delta\nu_L$ is the line width at half power in cycles per sec and T_L is the excess of brightness temperature in the line above that in the continuum. E is the 'emission measure' in parsecs (pc) cm^{-6}. As noted by Hoglund and Mezger[4], equation (1) should be a reasonable approximation for an optically thin line of Gaussian shape. From Oster's[5] equation (162) we obtain the free–free continuum radiation. If we assume that the continuum is optically thin and set ν = 1,680 Mc/s and T = 10^4 in the Gaunt factor,

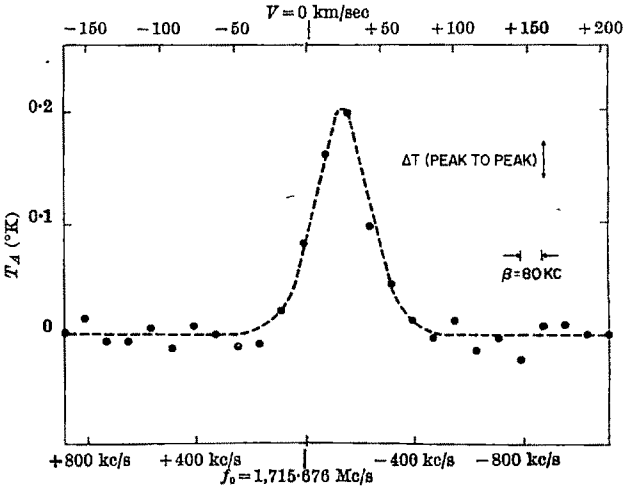

Fig. 1. Line spectrum for *M*17 ($n_{157} \rightarrow n_{156}$). The ordinate is antenna temperature. The abscissae are frequency and velocity with respect to the local standard of rest. A baseline slope of 0·10° K/Mc/s has been removed

Table 1. Summary of Observational Results

	$M17$ $\{\alpha=18h\ 17{\cdot}8m,\ \delta=-16°\ 09'\}$ 1950		$W51$ $\{\alpha=19h\ 20{\cdot}8m,\ \delta=+14°\ 08'\}$ 1950

$\Delta\nu_L$ (kc/s)	240	230	310	200
$\Delta\nu_L$ (corrected) (kc/s)	219 ± 60	209 ± 60	291 ± 80	172 ± 80
V (km/s)†	25 ± 5	21 ± 5	56 ± 6	64 ± 6

* Peak antenna temperature of the line above the continuum.
† The radial velocities are with respect to the local standard of rest.

we find for T_c, the brightness temperature of the continuum:

$$T_c = \frac{3{\cdot}13 \times 10^{17} E}{T_e^{1/2}\nu^2} \qquad (2)$$

Although the observed hydrogen lines are almost certainly optically thin, the continuum radiation at the centre of $M17$ may be optically thick at ~ 1,700 Mc/s. When the regions responsible for the continuum and line radiation originate in the same source (subtend the same solid angle), then the antenna temperatures are proportional to the brightness temperatures.

Eliminating E between equation (1) and equation (2) and solving for T_e in terms of the observed quantities, we obtain for $M17$ at 1,715 Mc/s, $T_e = 6{,}800° \pm 3{,}000°$ K, and at 1,651 Mc/s, $T_e = 5{,}500° \pm 2{,}400°$ K. The estimated errors include those in T_L, T_c and $\Delta\nu_L$. These temperatures were calculated with Gaunt factors adjusted to the respective temperatures rather than to the 10^4 °K used in the first approximation. If the continuum radiation originates in a region that is optically thick, the foregoing electron temperatures are too high. The electron temperatures for $M17$ are less than the value of 10^4 °K usually given for H II regions and greater than the value for $M17$ calculated by Hoglund and Mezger[4].

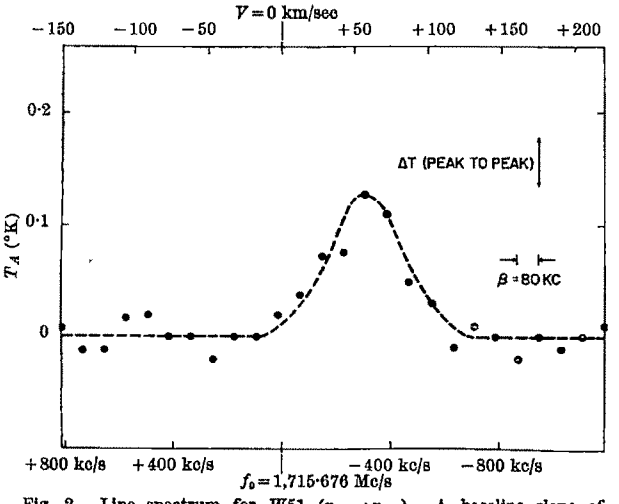

Fig. 2. Line spectrum for $W51$ ($n_{157} \rightarrow n_{158}$). A baseline slope of 0·20° K/Mc/s has been removed

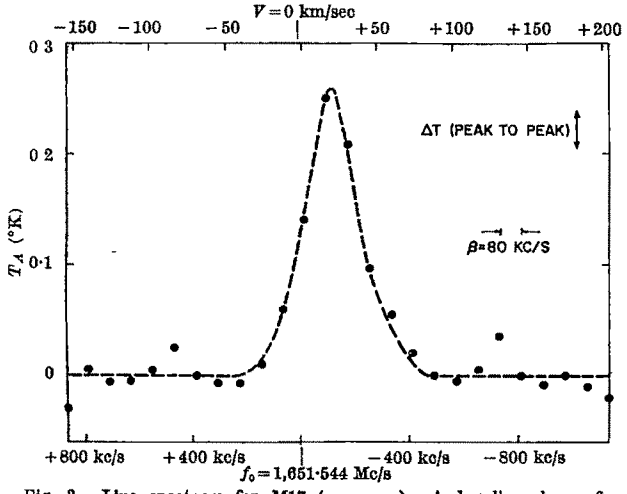

Fig. 3. Line spectrum for $M17$ ($n_{159} \rightarrow n_{158}$). A baseline slope of 0·25° K/Mc/s has been removed

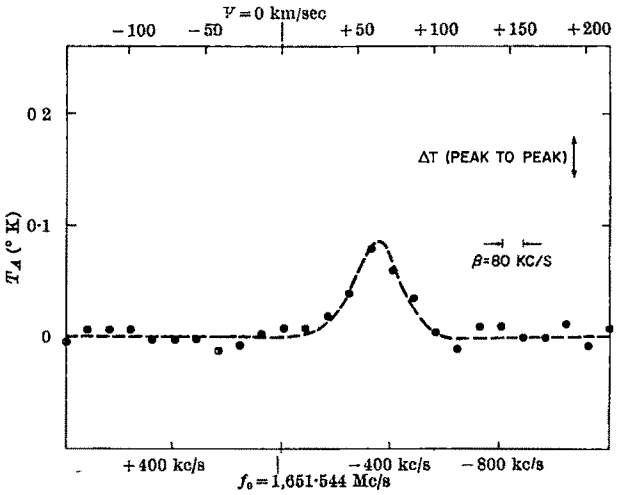

Fig. 4. Line spectrum for $W51$ ($n_{159} \rightarrow n_{158}$). A baseline slope of 0·12° K/Mc/s has been removed

We have not calculated T_e for $W51$ because of the small signal-to-noise ratio and, since the source is complex, we cannot determine what part of the continuum comes from the H II region responsible for the spectral line.

Kardashev gives formulae for broadening of the excited hydrogen lines by Doppler motion, turbulence, the linear Stark effect, and the statistical Stark effect. The relationship of the observed line-widths to the line broadening predicted by Kardashev is shown in Fig. 5. The two lines reported from the U.S.S.R., the line detected at the National Radio Astronomy Observatory, and the lines detected at Harvard University are plotted. The line broadening as predicted by Kardashev is marked $\Delta\nu_L$ and increases rapidly with increasing wave-length. We have obtained $\Delta\nu_L$ using Kardashev's equations 6, 7 and 8, $T_e = 10^4$ °K, $N_e = 10^2$ cm^{-3} and no turbulence. With these typical values assumed, the direct application of the Stark equations given by Kardashev predict a line width of an order of magnitude greater than that observed at $\lambda \sim 18$ cm.

Two additional reference lines are drawn for comparison with the observational data in Fig. 5. These are the straight lines which represent Doppler broadening only; the lower line for $T_e = 10^4$ °K (no turbulence) and the upper line for either $T_e = 10^5$ °K (no turbulence) or $T_e = 10^4$ °K and 40 km/sec turbulence. The observational data in Fig. 5 suggest that at least to $n \sim 160$ ($\lambda \sim 18$ cm) a combination of thermal broadening and a modest amount of internal turbulence within the nebula will entirely account for the observed line-widths. Moreover, there is observational evidence for internal motions within H II regions[5].

If the Stark equations as given by Kardashev were actually valid, we could find an electron density to generate the observed line-width at lower frequencies. If this procedure is followed for the source $M17$ we obtain $n_e = 10$ cm^{-3} (for $T_e = 10^4$ °K) and $n_e = 9$ cm^{-3} (for $T_e = 6 \times 10^3$ °K). With the electron density evaluated in this manner, we may use equation (1) to determine the size of the region, since $E \sim n_e^2\, l$. Using the observables in equation (1), an aperture efficiency of 0·38, and $n_e \sim 10$ cm^{-3}, we find a value of $l \sim 700$ pc to account for the observed T_L. This size and electron density may be compared with $l \sim 13$ pc and $n_e = 125$ cm^{-3} for the optical H II region given by Westerhout[7]. However, taking $n_e \sim 10$ cm^{-3}, $l \sim 700$ pc, and a distance to $M17$ of 1,700 pc[6], we can use equation (2) to evaluate the

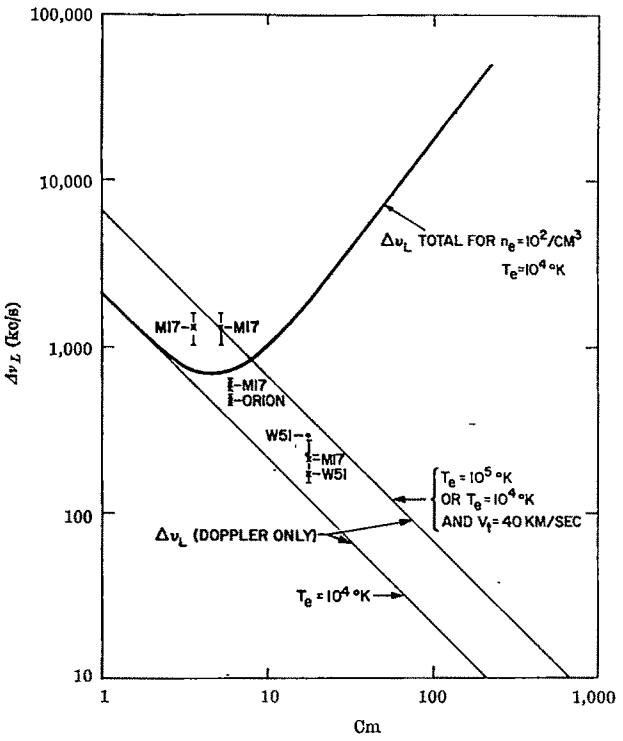

Fig. 5. Plot of line width ($\Delta\nu_L$) versus wave-length for all observed $n\rightarrow n-1$ lines. The error bracket shown for the Harvard data on *M*17 ($\lambda=18{\cdot}2$ cm) is typical of all four spectra

characteristics implied for the continuum. According to such a model, *M*17 would appear as a continuum source of very broad angular extent, but observations show no significant broadening in either the Harvard beam (52 arc min) or the Dwingeloo beam (34 arc min).

Consequently, the direct application of the Kardashev line-broadening theory leads to a contradiction with continuum observations, and grossly over-estimates the line-width. The fact that the theory was developed for a plasma having a much higher density than H II regions may be responsible for the over-estimate of the Stark effect. The importance of undertaking further observations at wave-lengths longer than 18 cm is evident in Fig. 5, and should help to clarify the problem of line broadening.

The successful detection of the $n\rightarrow n-1$ lines in thermal sources will allow astronomers to determine the galactic distribution of H II regions by methods similar to those developed for the 21-cm hydrogen line, bringing both ground state and excited hydrogen within the purview of radio telescopes.

We thank Patrick Palmer for his help in this investigation. Radio astronomy at Harvard University is supported by the U.S. National Science Foundation.

EFFECT OF GLASS CONTACT ON THE ELECTROPHORETIC MOBILITY OF HUMAN BLOOD PLATELETS

By Dr. J. R. HAMPTON and Dr. J. R. A. MITCHELL
Department of the Regius Professor of Medicine, Radcliffe Infirmary, Oxford

An important property of blood platelets is their ability to stick to each other, *in vivo* during thrombus formation and *in vitro* during the process of platelet aggregation. However, little is known about the actual mechanism of platelet to platelet adherence. Platelets carry a negative charge[1] and it has been suggested[2] that changes in this surface charge might be related to platelet aggregation. The surface charge of a cell can be investigated by measurement of the electrophoretic mobility of the cell, but previous electrophoretic investigations of platelets have been directed towards the determination of the ionic groups responsible for the charge[3], or to estimations of mobility in patients with various clinical conditions[4,5].

We have investigated the electrophoretic mobility of human platelets and have shown (unpublished) that changes can be induced by the agents known to cause platelet aggregation. During these investigations we found that platelet mobility also changes in the absence of aggregating agents, and that this change was markedly affected by glass contact. This article sets out the results of our investigations of these changes in platelet mobility which occur in the absence of exogenous aggregating agents.

Platelet-rich plasma (PRCP) was prepared from venous blood as described by Emmons and Mitchell[6], and platelet-poor plasma (PPP) was prepared by centrifuging PRCP in siliconized tubes at 750*g* for 15 min. Mobility measurements were made on a mixture of 9 vol. PPP and 1 vol. PRCP, using the horizontal capillary electrophoresis apparatus developed by Bangham *et al.*[3]. All estimations were carried out at 25° C, using a potential gradient of 2·66 V/cm. Only platelets in the stationary layer[3] were studied and, to eliminate the effect of drift, five transits in each direction were timed. The eyepiece graticule was calibrated against a stage micrometer under water, and the mean transit times were converted into mobility rates, expressed in μ/sec/V/cm.

When platelet electrophoretic mobility was measured twice on freshly separated plasma samples, it was found that the first measurement always gave a faster result than the second, and that subsequent measurements gave decreasing mobilities until a stable figure was reached. The rate of decrease in mobility varied from subject to subject, but all reached a stable minimum mobility within 1 h. Thereafter the mobility did not change and duplicate estimations on 36 samples in this stable state gave a mean difference between measurements of 1·16 per cent. It was also found that bringing the fresh plasma samples into contact with a non-siliconized glass surface immediately reduced the platelet mobility to this minimum, and that ageing thereafter had no effect. Samples were brought into contact with non-siliconized glass by placing them in a test-tube which had been washed only with tap water and distilled water, covering the tube with 'Parafilm' and gently inverting twelve times. This process will be referred to as 'glass contacting', and the treated mixture as 'post-contact plasma', while a PRCP/PPP mixture which had not been so treated and which had only encountered siliconized surfaces will be referred to as 'pre-contact plasma'. The reduction in mobility which we observed after glass contacting will be referred to as the 'contact effect'.

(1) *Effect of ageing on pre-contact mobility.* The pre-contact mobility of one aliquot of platelets was measured. Between 15 and 20 min later, the pre-contact mobility

of a second aliquot which had been kept at room temperature was measured and was shown to be reduced. Both samples were then brought into contact with non-siliconized glass in the way already described and their post-contact mobilities measured: they were found to be slower. The mean mobilities from six experiments are shown in Table 1: the mean values and their significance-levels were calculated from the transit times, so that each figure in Table 1 represents the mean of sixty transit times. Once the stable, post-contact state had been reached either by glass contact or by ageing, a second exposure to a glass surface had no effect, nor did further ageing for several hours.

If the manoeuvres involved in the glass contacting process were performed in a siliconized tube the decrease in mobility did not occur. It is therefore the contact with the non-siliconized glass surface, and not agitation or contact of platelets with air, which causes the decrease.

(2) *Effect of siliconized and non-siliconized glassware.* Blood samples were collected by a two-syringe technique from a single venepuncture. The first syringe was siliconized, while the second was not, and the samples were afterwards handled in siliconized and non-siliconized glassware respectively. The pre-contact mobility of the platelets handled in the non-siliconized system was equal to the post-contact mobility of those handled in the siliconized system. Glass contacting of the platelets from the non-siliconized system in the usual way caused no change in mobility. The mean results of six experiments are shown in Table 2.

(3) *Microscopical appearance of platelets.* If the viscosity of the suspending liquid remains constant, a change in the size of a particle will cause a change in its electrophoretic mobility. It was therefore possible that the reduction of platelet mobility on glass contact might be due to a change in the configuration of the platelet, or to pairs or small clumps of platelets developing. Platelets were examined by phase-contrast microscopy before and after glass contact and there was no difference in the frequency with which pairs or small clumps were seen in the pre-contact and post-contact samples, nor could any difference be detected in platelet morphology. The change in mobility must therefore be due to a change in the surface charge of the platelets, or to a change in the viscosity of the suspending medium.

(4) *Effect of contacting the platelet-poor plasma.* Instead of contacting the PRCP/PPP mixture in the usual way, the PPP alone was contacted and was then used to dilute pre-contact PRCP. The mobility of the platelets was unaffected and the usual slowing occurred when the whole PRCP/PPP mixture was contacted. The reduction of platelet mobility on glass contact is not due, therefore, to a change in viscosity of the platelet-poor plasma; it is also unlikely to be related to activation of the early stages of the clotting process, for this would have occurred when the platelet-poor plasma alone was contacted.

(5) *Suspensions of platelets in saline.* PRCP was prepared in the usual way, but, instead of using PPP as the diluent, 1 ml. portions were diluted with 8 ml. 0·85 per cent (w/v) saline and 1 ml. 3·8 per cent (w/v) trisodium citrate. The pre-contact mobility of the platelets was measured; the platelet–saline mixture was then 'glass contacted' in the usual way and the post-contact mobility of the platelets determined. The mean values obtained from six experiments were: pre-contact, 1·34 μ/sec/V/cm; post-contact, 1·26 μ/sec/V/cm (P for difference 0·01). It will be noted that both pre- and post-contact mobilities are higher than those found when the PRCP is diluted with PPP; this results from the lower viscosity of the saline mixture. Nevertheless, the contact effect still occurs when the platelets are suspended in citrate-saline.

(6) *Effect of ethylenediamine tetraacetic acid (EDTA).* Blood was collected in a siliconized syringe and 9 ml. portions were transferred to centrifuge tubes containing either citrate or 0·15 ml. of 10 per cent (w/v) dipotassium EDTA and 0·85 ml. normal saline. The contact effect in the EDTA tubes did not differ from that observed when citrate was used as the anticoagulant.

(7) *Effect of heparin.* 9-ml. aliquots of blood were collected into either 1 ml. sodium citrate or into 1 ml. normal saline containing varying concentrations of heparin; these were such as to give concentrations in the final mixture of 1, 2, 5, 10 and 50 units per ml. It was found that with concentrations of 2 units/ml. of heparin and above the contact effect was abolished: the pre-contact mobility was the same as the post-contact mobility of the citrate sample. With 1 unit/ml. of heparin the pre-contact mobility was lower than that of the pre-contact citrate sample, but fell to the same level after contact as the post-contact citrate sample. When heparin was given intravenously in a dose of 750 N.I.H. units, it abolished the contact effect in a blood sample taken 5 min later.

(8) *Effect of enzyme poisons.* A variety of enzyme poisons was added to a fresh PRCP/PPP mixture in siliconized tubes; control tubes containing saline were prepared at the same time. Each was incubated at 25° C for 5 min and their pre-contact mobility measured. Both series were then contacted and their post-contact mobilities measured. It was found that *N*-ethylmaleimide in concentrations up to 10^{-2} M and *p*-hydroxymercuribenzoate 10^{-3} M (inhibitors of reactions involving sulphydryl groups), potassium cyanide $1{\cdot}5 \times 10^{-3}$ M (inhibitor of cytochrome oxidase), sodium fluoride $2{\cdot}5 \times 10^{-4}$ M (inhibitor of synthesis of phosphopyruvate), and sodium monofluoroacetate 10^{-2} M (inhibitor of aconitase, and so of the tricarboxylic acid cycle) had no effect on the pre-contact mobility, its reduction on glass contact, or the post-contact mobility of the platelets.

However, when the enzyme poisons were added to the citrate into which the blood was collected a different pattern emerged. *N*-ethylmaleimide at 10^{-3} M abolished the difference between pre- and post-contact mobilities, although the post-contact mobility was the same as that of a parallel sample taken into citrate alone. *N*-Ethylmaleimide 10^{-5} M had no effect, and 10^{-4} M an intermediate effect. *p*-Hydroxymercuribenzoate 10^{-3} M similarly abolished the difference between pre- and post-contact mobilities, while potassium cyanide, sodium fluoride and sodium monofluoroacetate had no effect.

(9) *Effect of pyruvate kinase.* In view of our finding that low concentrations of adenosine diphosphate (ADP) increase the electrophoretic mobility of platelets (unpublished), it seemed possible that the reduction of platelet mobility on glass contact might be due to loss from the platelet surface of ADP. ADP can also be removed from a system[7] by the enzyme pyruvate kinase (PK) acting through the reaction:

$$\text{Phosphoenolpyruvate (PEP)} + \text{ADP} \overset{\text{PK}}{\rightleftharpoons} \text{Pyruvate} + \text{ATP}$$

In this reaction the equilibrium lies far to the right. Blood was collected in the usual way and 8-ml. portions were transferred to centrifuge tubes containing 1 ml. sodium citrate and 1 ml. of a PEP–PK mixture in saline. Control tubes containing citrate and saline alone or citrate plus saline solutions of PEP or PK were also prepared.

PEP in a concentration in the final mixture of 0·005 μg/ml. did not have any effect on the pre- or post-contact

Table 1. Effect of Age and Glass Contact on Platelet Mobility

	Mean pre-contact mobility (μ/sec/V/cm)	Mean post-contact mobility (μ/sec/V/cm)	P for difference
Fresh platelets	1·18	1·10	< 0·001
Platelets 15 min old	1·14	1·11	*N.S.*
P for difference	0·03	*N.S.*	

Table 2 Effect of Siliconized and Non-siliconized Glassware on Platelet Mobility before and after Glass Contact

	Mean pre-contact mobility (μ/sec/V/cm)	Mean post-contact mobility (μ/sec/V/cm)	P for difference
Siliconized	1 18	1·03	< 0 001
Non-siliconized	1·02	1·03	*N S.*
P for difference	< 0 001	*N.S*	

mobility of the platelets. With 0·05 and 0·5 μg/ml. a progressive reduction in both pre- and post-contact mobility was produced, but the difference between the two was the same as in the control sample; the contact effect was thus unchanged. PK alone in a concentration of 0·1 mg/ml. in the final mixture had no effect on either pre- or post-contact mobility.

When both PEP and PK were present the difference between pre- and post-contact mobilities was abolished: this occurred with concentrations of PEP as low as 0·0005 μg/ml. and PK 0·01 mg/ml. The post-contact mobility was not, however, different from that of the control sample.

Contact with a glass surface causes a reduction in the electrophoretic mobility of platelets: this could be due to a reduction in their surface charge, to an increase in their size, or to an increase in the viscosity of the plasma in which they are suspended. A change in plasma viscosity is unlikely to be the cause of the change in platelet mobility since glass contact of platelet-poor plasma before it is mixed with the platelet-rich plasma has no effect; a viscosity change is also unlikely to be important because platelets are still affected by glass contact when one volume of PRCP is diluted with 9 vol. of saline. Microscopy shows that there is no apparent change in the size or shape or degree of aggregation of the platelets, and so it seems most likely that the reduction of mobility on glass contact is due to a decrease in the surface charge of the platelet. Since most previous investigators have used washed platelets it is not surprising that this difference in mobility before and after glass contact should not have been noticed before: Zucker and Levine[5] found that the mean mobility of washed platelets was lower than that before washing, but they did not consider the difference significant.

Initially it seemed possible that the change in mobility on glass contact was due to adsorption by the platelet of factors XII or XI which are activated by glass surfaces. This stage of blood coagulation is not calcium dependent, so the failure of EDTA to abolish the contact effect would be acceptable. However, our inability to produce the effect by contacting the PPP on its own makes this explanation unlikely and it is clear that it is contact of the platelets themselves with glass which mediates the effect.

The reduction of platelet mobility on glass contact is apparently related to reactions involving sulphydryl groups, for it is these reactions which are inhibited by *N*-ethylmaleimide and *p*-hydroxymercuribenzoate. Since the blood has to be collected into the enzyme poisons for them to have any effect, it seems possible that their action is to inhibit some change, which occurs during the production of PRCP, and which results in an increase in mobility. This increased mobility can then be reduced by glass contact.

When blood is collected into the ADP-removing PK/PEP system the contact effect is abolished; this suggests that ADP is in some way involved. The addition of low concentrations of ADP to a PRCP/PPP mixture causes an increase in platelet mobility: ADP is negatively charged and it seems likely that it is adsorbed on to the platelet surface increasing its net negative charge, and so causing an increase in electrophoretic mobility. Bringing the platelet into contact with glass may then remove the ADP; we have shown that ADP is affected by glass contact, for if a solution of ADP is brought into contact with an unsiliconized glass surface its effects on platelet mobility are much diminished. We therefore suggest that during the production of PRCP, ADP or some similar substance becomes adsorbed on to the platelet surface: possibly it is released by red cells or by the platelets themselves as a result of centrifuging. When the platelets come into contact with unsiliconized glass the ADP is either removed or inactivated; a similar process occurs at a slower rate if the platelets are in siliconized glassware.

We thank Sir George Pickering for advice and encouragement, and Dr. A. D. Bangham for helpful discussions on the problems of cell electrophoresis and surface charge.

INTERCELLULAR SPACE IN NORMAL HUMAN STRATUM CORNEUM

By Dr. ISSER BRODY

Department of Dermatology, Karolinska Hospital, and Department of Anatomy, Karolinska Institute, Stockholm, Sweden

HISTOLOGISTS have disagreed on the question of whether or not there is an intercellular space in the stratum corneum. Pernkopf and Patzelt[1] assumed the existence of an intercellular space containing a substance which could be stained with silver nitrate. According to other authors, such as Weidenreich[2], Hoepke[3] and Lever[4], such an intercellular space does not exist. Modern histochemical research has also been unable to give a definite solution to this problem. Wislocki *et al.*[5] have demonstrated a weak persistence of periodic acid–Schiff-positive intercellular substance in the horny layer of plantar skin. Kligman[6], on the other hand, could not discern any intercellular substances in isolated sheets of the stratum corneum.

In order to elucidate the function of the horny layer as a barrier, investigations were undertaken of the horny cell itself. The cell membranes have been allocated a central part in this research effort, mainly following the comprehensive investigations of Unna[7] on the different degrees of solubility of the horny substances. When the stratum corneum is treated with nitric acid or cold alkaline solutions a membrane-like component insoluble in these chemicals is all that remains of the stratum corneum[7]. The investigations initiated by Unna have been extended, and his hypothesis that the cell membrane constitutes the most resistant component of the horny layer (Unna's keratin *A* (ref. 7)) has been generally accepted[1–3,6,8–10].

The assumption that the membrane-like structure demonstrated in the light microscope represents the cell membrane of the horny cell is, however, incompatible with electron-microscopical investigations of the plasma membrane in the stratum corneum. The plasma membrane has a thickness of about 200 Å (to be published), which is below the capabilities of the light microscope. Furthermore, no peripherally located intracellular component is discernible in the electron microscope which, as a consequence of the preparation technique, might fuse with the plasma membrane to form a membrane-structure corresponding to that observable in the light microscope. Thus the inference, therefore, is that the structures considered by histologists to be cell membranes either constitute

components located in a space between the cells or are artefacts due to the preparation technique for light microscopy.

An intercellular space has been definitely demonstrated by means of electron microscopy[11–17]. Only few observations of intercellular components have been made[13–17]. Usually the intercellular space appears electron-optically empty. A more detailed electron-microscopic investigation of the intercellular space was therefore deemed necessary, in order to localize the aforementioned membrane-like structure in the normal human stratum corneum. The problem of the possible dissolution of structural components during the process of tissue preparation for electron microscopy was considered to be of particular importance in this connexion. For this reason the time factor with respect to fixation, rinsing and dehydration has also been made the subject of electron-microscopic investigation. The findings will be reported here and discussed in relation to the aforementioned histological view concerning the localization of the membrane-like structure. Furthermore, in the light of the results obtained, the barrier function of the horny layer has been re-evaluated and an important role of the intercellular space has been emphasized.

Normal skin from the lateral abdominal and sacral regions from four men and four women, aged 30–50 years, was used. The tissue was fixed in a 1 per cent osmium tetroxide solution buffered with veronal-acetate to *p*H 7·2–7·4 (ref. 18) and made isotonic to blood by the addition of sodium, potassium and calcium chloride[19]. The temperature during fixation, rinsing in Tyrode's solution and dehydration to the stage of 95 per cent ethyl alcohol was about 5° C. The treatment of the tissue was carried out according to the following schedule:

Osmium tetroxide	30 min
Tyrode's solution	5 ,,
Ethyl alcohol (70 per cent)	20 ,,
Ethyl alcohol (95 per cent)	10 ,,
Ethyl alcohol (abs.)	60 ,,
Propylene oxide	60 ,,

The tissue was embedded in 'Epon'[20] and cut perpendicularly to the skin surface with an LKB 'Ultrotome'. All sections were stained with a saturated water solution of uranyl acetate at 60° C for 20 min[13] and with lead tartrate according to Millonig[21]. The sections were examined in an RCA EMU 3 A electron microscope.

The width of the intercellular space. In the cross-sections of skin from both the abdominal and sacral regions the intercellular space between the desmosomes shows a conspicuous variation in width from 300 Å to 20,600 Å. This variation occurs very irregularly and is not restricted to any particular sub-layer of the stratum corneum (Figs. 1–3).

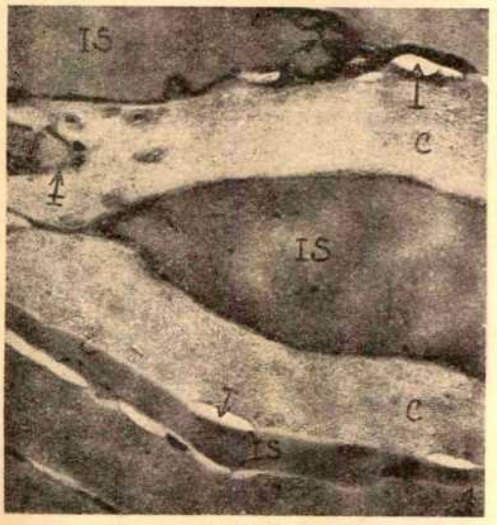

Fig. 1. Part of the basal sub-layer in normal human stratum corneum. The intercellular space (*IS*) varies considerably in width. It is filled with a non-homogeneous substance. A highly opaque membrane-like component (⟶) appears mainly at the periphery of the intercellular space. Small electron-optically empty areas (|⟶). The cytoplasm of the cells (*C*) shows fibrils with a keratin pattern. Granule of unknown nature (||⟶). (× 32,000)

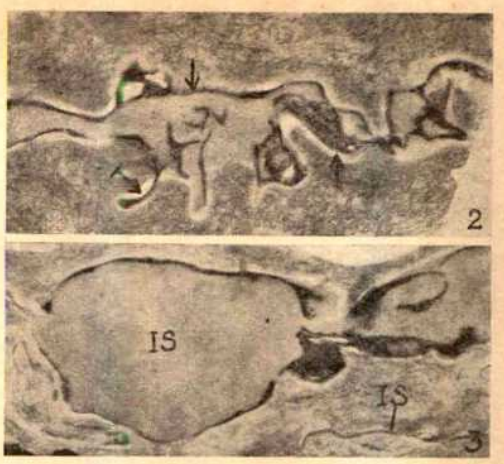

Fig. 2. Part of the intermediate sub-layer. The intercellular space is filled with a non-homogeneous substance. At the periphery of the intercellular space appears the highly opaque membrane-like component with its incorporated bodies (⟶). Small electron-optically empty areas close to the cell surface (|⟶). (× 16,000)

Fig. 3. Part of the superficial sub-layer. The intercellular space (*IS*) varies distinctly in width. It is filled throughout with a non-homogeneous substance. The highly opaque membrane-like component with its incorporated bodies appears at the periphery of the dilated parts of the intercellular space. (× 11,200)

The cells display a longitudinal, flattened shape. At either end they taper off in projections of different length, interlocking like cog-wheels. In the regions where the adjacent cells dovetail with each other the intercellular space generally seems to be narrow, but here, too, distinct variations in the width are observable.

Intercellular components. In the horny layer the intercellular space is filled throughout with a non-homogeneous substance showing moderate opacity (Figs. 1–3). In higher magnification this substance displays a pattern with indications of fine, opaque filaments. Small electron-optically empty areas are occasionally seen, for the most part close to the cell surface. Embedded in the non-homogeneous substance are a membrane-like component and granules of different shape, size and ultrastructure.

The membrane-like component displays a high opacity (Figs. 1–5). It appears mainly at the periphery of the intercellular space close to the cell surface, but is distinctly separated from the plasma membrane (Fig. 5). It may be observed along the length of the cells or may occur only fragmentarily. In some areas it displays a triple-layered pattern and in others it appears as a single, blurred layer. The membrane varies here between 100 and 400 Å in thickness. In other parts, again, bodies with a length of 2400–7300 Å and a breadth of 450–5100 Å are incorporated in the membrane-like structure. These bodies occur with greater or lesser frequency and contain both a highly opaque material which occasionally displays a laminated arrangement, and a less opaque substance (Figs. 2–4).

Granules containing triple-layered membranes are often observed (Fig. 6). It is, however, not yet clear whether the outer, bounding membrane is single- or triple-layered. The granules have a length of 2700–5200 Å and a breadth of 1500–2200 Å.

Another larger type of granule seems to be at least partly constituted of a system of triple- and multi-layered membranes (Fig. 9). In the present investigation only certain parts of these granules could be observed, and hence it is accordingly not possible to give any more exact indication of their size.

A typical granule is shown in Fig. 7. Its ultrastructure is diffuse. It seems to be bounded by an opaque, single layer. It has a rather low opacity, but some parts appear

to be more, and others less, opaque. It is about 3600 Å in length and about 1300 Å in breadth. Close to such a granule smaller, dense opaque granules are often observed.

Another type of granule appears as mainly dense corpuscles with a round or oval shape (Fig. 8). These vary in size and opacity[16]. They have a length of 170–1300 Å and a breadth of 170–900 Å. A granule or vesicle bounded by a rather broad, opaque membrane adjacent to which appear smaller granules can also be seen in Fig. 8. It has a length of about 3200 Å and a breadth of about 2300 Å.

Effect of the Time Factor with Respect to Fixation, Rinsing and Dehydration

The width of the intercellular space. As clearly emerges from this investigation, the intercellular space varies considerably in width. This variation is distinct in all sub-layers of the stratum corneum. Similar observations have been made in other investigations[11–17]. Variations in the time of fixation, rinsing and dehydration do not appear to affect the width of the intercellular space.

Since in earlier investigations the intercellular space usually appeared to be electron-optically empty, the widened parts have been considered as simply "enlarged and emphatic artefacts" due to the preparation technique for electron microscopy[6]. Without adducing any experimental foundation it has been asserted that the intercellular space is of a sub-microscopic order of magnitude[6]. Thus Kligman[6] points out that "if one knows the thickness of the horny layer and the number of cell layers, the thickness of the individual cells can be indirectly calculated". However, the present investigation shows quite clearly that the intercellular space constitutes an essential part of the stratum corneum and that it is not possible to get away from this when determining the thickness of the latter. Throughout the horny layer the cells show a variation in height of between 1,200 and 23,400 Å. The width of the intercellular space is 300–20,600 Å. There is no doubt that the intercellular space and its substances are affected by the preparation technique to the same extent as the rest of the tissue. However, throughout the stratum corneum the intercellular space is filled with a non-homogeneous substance irrespective of whether the intercellular space is wide or narrow. In this substance are embedded different structures, some of them of a size discernible under the light microscope. These observations may very well support the assumption that the intercellular space *in vivo* is also subject to wide variations in width.

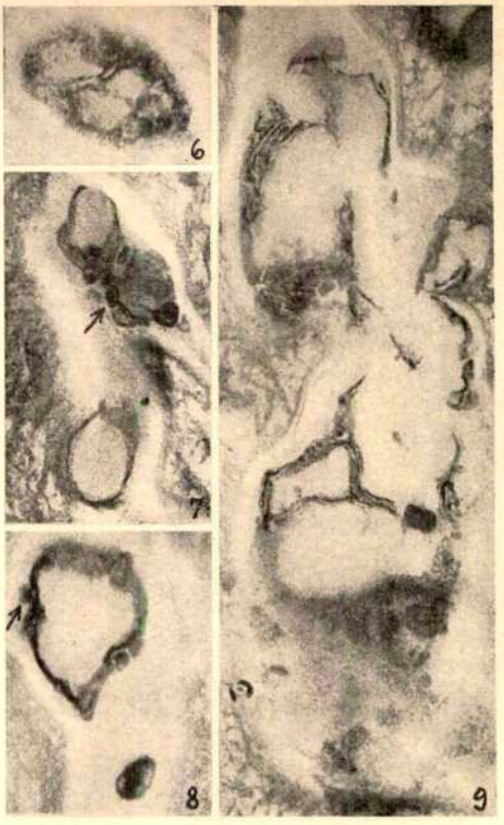

Fig. 6. Granule displaying a triple-layered inner membrane. The outer, limiting membrane is indistinct. (× 84,000)

Fig. 7. The granules seem to be partly bounded by an opaque, single-layered membrane. Some parts of the granules are more, and others less, opaque. Small, opaque corpuscles (⟶) occur close to the longitudinally sectioned granule. (× 60,800)

Fig. 8. At the bottom a small, oval granule with a varying opacity. In the left upper corner of the picture a granule or vesicle bounded by a rather broad, opaque membrane. Small corpuscles (⟶) appear close to the membrane. (× 70,400)

Fig. 9. Disrupted granules which partly consist of triple- and multi-layered membranes. (× 60,800)

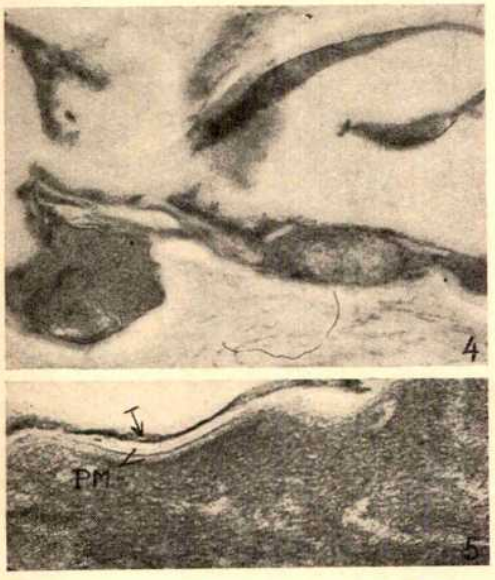

Fig. 4. Higher magnification of Fig. 3 showing bodies incorporated in the membrane-like component. The bodies partly display a laminated arrangement. (× 35,200)

Fig. 5. Part of a cell in the superficial sub-layer. The cytoplasm consists of rather opaque keratin fibrils and small areas with a less opaque substance. The cell is bounded by a plasma membrane (*PM*). This consists of a broad cytoplasmic zone, a narrow intermediate, and a narrow outer layer. The highly opaque membrane-like component (⟶) is located in the intercellular space distinctly separated from the plasma membrane. (× 127,200)

The non-homogeneous substance. In earlier investigations of the horny layer the intercellular space usually appeared electron-optically empty. However, small remains of a non-homogeneous substance were observable in the intercellular space in the basal and intermediate sub-layers, but never in the superficial layer[13–15]. In these investigations the tissue has been fixed, rinsed and dehydrated for long periods according to the following schedule: osmium tetroxide, 4 h; Tyrode's solution, 1 h; ethyl alcohol (70 per cent), 3 h or overnight; ethyl alcohol (95 per cent), 1 h; ethyl alcohol (abs.), 1–2 h.

From the present investigation it emerges that the non-homogeneous substance is not a material that is broken down in the stratum corneum to facilitate the flaking off of the cells at the skin surface but fills the intercellular space throughout the horny layer, that is, also in the superficial sub-layer. It is, on the other hand, sensitive to the preparation technique and is best retained with short fixation, rinsing and dehydration periods. However, even when the time factor for fixation, rinsing and dehydration has been considerably reduced (as in this investigation), empty areas are still electron-optically visible in the intercellular space. Further investigations are being carried out to elucidate which stage in the

processing for electron microscopy is most deleterious for this substance.

A non-homogeneous substance has also been distinctly observed in the intercellular space in parakeratotic horny layers, for example, in psoriasis[15,22,23] and in atopic dermatitis (to be published). In these investigations of parakeratosis, however, long fixation, rinsing and dehydration times have been used according to the schedule already given. This would support the assumption that the non-homogeneous substance is less easily dissolved in the parakeratotic horny layers than that in the normal stratum corneum. The different solubility of the intercellular non-homogeneous substances in ortho- and parakeratosis might be interpreted as an expression for differences as to their chemical composition.

The membrane-like component and granules. In electron-microscopic investigations in which the schedule for long periods of fixation, rinsing and dehydration was used, components similar to the membrane-like structure and the different granules described here appeared in the intercellular space; this was irrespective of whether the non-homogeneous substance was retained or not[13,15–17]. In an investigation of the horny layer in guinea-pig epidermis[13], two types of intercellular bodies were observed. One type displayed a diffusely outlined ultrastructure with a laminated arrangement. This represents what was there assumed to be a desmosome. The other type showed vesicular structures with an outer, highly opaque membrane. These components were also interpreted to be desmosomes, but they may actually correspond to some of the granules observed in this investigation. Their length is between 750 and 5700 Å and their breadth between 550 and 4600 Å.

The observations of the aforementioned components in the intercellular space even in the superficial sub-layer of the normal human stratum corneum, where the non-homogeneous substance has always been dissolved when long fixation, rinsing and dehydration times have been used, favour the idea that they suffer less from the preparation technique than does the non-homogeneous substance.

Electron-microscopic Localization of Unna's Keratin A

Optical microscopy may be used for the study of structures down to about 2000 Å (ref. 24). Several of the bodies incorporated in the membrane-like component and several of the different granules are of such an order of magnitude that they may be seen in the light microscope, and may give the impression of a diffuse membrane-like structure if they occur closely enough. Granules and bodies the size of which are close to the lower limit of the resolution of the light microscope may also be discernible by means of optical microscopy if they are numerous and occur densely in the intercellular space.

Matoltsy and Parakkal[9] treated plantar human skin and bovine oral epithelium with 0·1 N sodium hydroxide and after centrifugation obtained a membrane-like structure which they examined in the electron microscope. They assumed that this structure represented isolated envelopes of the horny cells, in accordance with the view earlier suggested by histologists[1–3,6–10]. However, this structure is very similar in arrangement to the membrane-like component described in the present investigation. The thinnest parts of their membrane seem to be about 160 Å and the thickest about 5400 Å, that is, it rather closely agrees, also in point of thickness, with the membrane-like component in the present investigation, also where the aforementioned bodies occur.

The membrane-like component shown here should not be confused with the plasma membrane of the cells. The former is definitely located in the intercellular space and is distinctly separated from the plasma membrane. The membrane-like component varies in thickness between 100 and 5150 Å, whereas the plasma membrane in all its parts is about 200 Å thick (to be published). There are, furthermore, distinct ultrastructural differences between these two structures. Thus the plasma membrane displays an asymmetric triple-layered pattern consisting of a broad, opaque cytoplasmic zone, an intermediate narrow layer with low opacity and an outer, opaque narrow layer facing the intercellular space (Fig. 5). Finally, the membrane-like component has a much higher opacity than the plasma membrane.

These different observations seem to justify the suggestion that the diffuse membrane-like structure observed in the light microscope and retained in the horny layer after skin has been treated with cold alkaline solutions or nitric acid does not represent the cell membrane as has generally been assumed[1–3,6–10], but is constituted by a complex of opaque components in the intercellular space. These are the only structures which are of a size recognizable in the light microscope, whereas the plasma membrane itself is of a submicroscopic order of magnitude. If this were the case, the membrane-like component and the different granules demonstrated in the present investigation would represent what histologists have considered as the most resistant material in the horny layer, or what Unna[7] has called 'keratin *A*'.

In this connexion, it is of interest to mention the investigations by Szodoray[25] and Matoltsy and Matoltsy[26] on the non-cornified epidermis. Szodoray treated skin sections with trypsin and obtained a membrane-like structure in the upper Malpighian layer, which, he assumed, represented the cell membrane. Matoltsy and Matoltsy[26] extended the investigations of Szodoray[25], confirmed his results and gave them the same interpretation. These authors exposed 2-day-old rat skin to the effect of 1·0 per cent trypsin. They pointed out "that trypsin attacks and disperses all components of the granular cells except the keratohyaline granules and cell membranes". It is difficult to measure exactly the membrane, which they thought to be the cell membrane, but it seems to vary between 300 and 2300 Å in thickness. This structure thus differs distinctly in thickness from that of the plasma membrane. The plasma membrane of the non-cornified cells is about 80 Å (ref. 9). On the other hand, important changes of the cell surfaces and the intercellular space are observed in the stratum intermedium as compared with the strata below. Whereas the intercellular space is mainly electron-optically empty and the cell surfaces display protrusions in the strata basale and spinosum, the cell surfaces in the stratum intermedium show invaginations[14,27–29]. The invaginations and the rest of the intercellular space in the stratum intermedium are filled with a non-homogeneous substance and granules[9,14,27–30]. Some of these granules agree in ultrastructure with the intracellular so-called Odland's bodies[9,14,27–33]. The granules in the invaginations have a size of 1000–5000 Å (ref. 9). They have a size similar to that of the bodies incorporated in the membrane-like component shown in the present investigation. Thus, in accordance with the aforementioned discussion on the horny layer, it is only the intercellular material that is visible in the light microscope, and not the 80-Å-thick plasma membrane. There is, therefore, no electron-microscopic support for the theory first proposed by Unna[7] that the cell membrane represents the most resistant component in the horny layer, nor for the hypothesis based on the investigations by Szodoray[25] and Matoltsy and Matoltsy[26] to the effect that the formation of these resistant cell membranes commences in the stratum intermedium.

On the basis of the present investigation it may be suggested that the keratinization process in the epidermis implies not only the transformation of a stratum basale cell into a horny cell with the formation of keratinous and non-keratinous material and of a modified plasma membrane, but also—which may be equally important—the appearance of structures in the intercellular space. These

structures first appear in the intercellular space in the stratum intermedium[9,14,27–30]. The hypothesis has been put forward that the so-called Odland's bodies are excreted from the cells into the intercellular space in the stratum intermedium[9,30]. The changes of the cell surfaces, with protrusions in strata basale and spinosum and invaginations in stratum intermedium[28], may support this view. The intercellular granules are not, in contradistinction to the findings of Matoltsy and Parakkal[9], restricted to the stratum intermedium, but, as is shown in the present investigation, distinctly discerned in the whole stratum corneum.

Barrier Function of the Horny Layer

The discussion of the stratum corneum as a barrier has mainly pivoted on the question as to whether the barrier is located in the basal part of the horny layer[34–37], or includes the whole stratum corneum[6,38]. The route of penetration of substances from without into the skin and vice versa was earlier thought only to be transcellular, but since an intercellular space has been demonstrated by electron microscopy, a penetration through the intercellular space has also been discussed as a possibility[39,40]. However, it has been suggested that the electron-microscopic finds may be artefacts, and if an intercellular space does really exist it has been assumed to be only of a submicroscopic order of magnitude[6].

Nothing is as yet known about the chemical composition of the intercellular material. In accordance with the histological view that no intercellular space exists[2–4], no such space has been postulated in the chemical and X-ray diffraction investigations of the stratum corneum (on lipids, water-soluble substances, etc.) and the results have been referred only to the horny cell itself.

The present investigation supports the hypothesis that the whole stratum corneum constitutes the barrier[6,38]. The barrier, however, is formed both of the cells and the intercellular space. The intercellular space contains a complex of structures. It is filled with a non-homogeneous substance which shows indications of a pattern with filaments. In this substance appear opaque components which are here assumed to constitute Unna's so-called keratin *A* (ref. 7). The non-homogeneous substance shows greater solubility than these components for the preparation technique. These observations may favour the suggestion that the penetration rate of chemicals and solvents may be due to the amount of various opaque components, that is, the membrane-like component with its incorporated bodies and the different granules embedded in the non-homogeneous substance. Variations of this amount could explain the differences in the penetration rate at different levels or in adjacent areas of the horny layer and in different sites of the body.

In a similar way the barrier function of the stratum intermedium may be in part regulated by the intercellular material in this layer.

REPRESSION AND THE CONTROL OF CYCLIC ENZYME SYNTHESIS IN *Bacillus subtilis*

By Dr. MILLICENT MASTERS and Dr. W. D. DONACHIE*
Institute of Animal Genetics, University of Edinburgh

THE synthesis of many enzymes is periodic in synchronous populations of *Bacillus subtilis*[1–4]. The synthesis of each enzyme occupies only a fraction of the cell cycle and the quantity of enzyme does not increase thereafter until the next cell cycle; thus the total amount of enzyme in a synchronous culture increases in a stepwise fashion. Since the synthetic periods of different enzymes are not simultaneous, a linear map can be constructed which represents the temperal order of synthesis of the different enzymes. This article reports experiments designed to discover what mechanisms determine the timing of these synthetic periods.

It has been suggested that the sequential duplication of the genome of *B. subtilis*[5] might in some way determine the order of enzyme synthesis. Indeed, Masters and Pardee have reported that the order of synthesis of four enzymes corresponds to the order of replication of their genes[4]. Various hypotheses have been advanced to explain the

* Present address: M.R.C. Microbial Genetics Research Unit, Hammersmith Hospital, Ducane Road, London, W.12.

discontinuous enzyme syntheses and the way in which they appear to be related to the order of replication of the genes. These can be summarized as follows: (1) Enzymes are synthesized immediately after the replication of their structural genes[1] but not at other times. (2) Transcription is ordered in the same way as replication but does not necessarily occur simultaneously with replication. A corollary of this hypothesis would be that each gene may be transcribed at only one time during each cell cycle. (3) Periodic enzyme synthesis is the result of end-product repression. Enzyme and end-product form a system in which the concentration of one determines the rate of synthesis of the other. As a consequence of these interactions the intracellular concentrations of both enzyme and end-product oscillate[2,6,7]. According to this explanation, the order of enzyme synthesis may, but need not be, the same as that of gene replication.

Our evidence is consistent with the third explanation since we have shown that periodic enzyme synthesis continues in the absence of DNA synthesis and that the timing of synthetic periods can be altered by interference with repressor-levels.

The techniques for growing and synchronizing *Bacillus subtilis* (*W*23) and the methods used to assay enzyme activities and total DNA have been described previously[1,3]. The 5-fluorodeoxy uridine (FUdR) was a gift from Roche Products, Ltd.

Initiation of Enzyme Steps in the Absence of DNA Synthesis

In cultures of *B. subtilis* in which L-histidine is supplied as sole carbon source, DNA synthesis is periodic. As shown in Fig. 1, the DNA synthetic period occupies about 50 min of a cell cycle of 120 min.

Consequently there is no DNA synthesis during about 60 per cent of the cell cycle in histidine medium. However, the times of initiation of autogenous[2] steps in the synthesis of the enzymes histidase, aspartate transcarbamylase (ATCase), ornithine transcarbamylase (OTCase) and dehydroquinase (DHQase) are spaced over a period equal to the whole cell cycle[4]. It is clear that the initiation of some of these syntheses must occur during the period when no DNA is replicating. (Similar observations have been made on the yeast *Schizosaccharomyces pombe*[10].)

Direct evidence that periodic enzyme synthesis can continue in the absence of DNA replication was obtained by preventing DNA synthesis with FUdR[8,9]. Since strain *W*23 was not susceptible to this drug, a prototrophic revertant (23*TR*) of a thymineless strain (23*T*⁻) (ref. 11) was used. In this strain DNA synthesis was almost completely inhibited for at least 2 h following the addition of FUdR. During this period optical density and cell length continued to increase. Cell division, however, was inhibited and viability decreased exponentially.

A synchronous culture of 23*TR* was divided into two parts and FUdR added to one of them (Fig. 2). The subsequent synthesis of OTCase was followed in the two cultures. In both cases enzyme synthesis continued to be

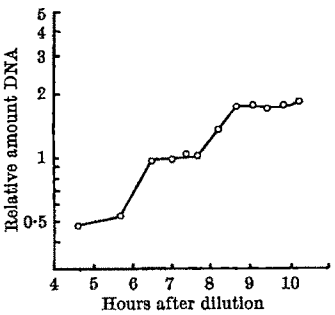

Fig. 1. DNA synthesis in a synchronous culture of *W*23 growing on minimal medium[12] with 0·2 per cent L-histidine as carbon source. Total DNA was estimated in the hot perchloric acid soluble fraction of cold trichloroacetic acid precipitates by the method of Burton[14]

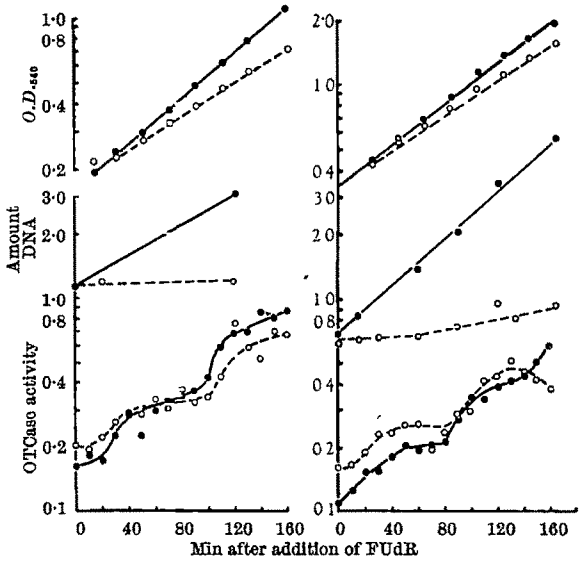

Fig. 2. DNA, $O.D._{540}$ and OTCase increase in two cultures of 23*TR* growing synchronously on minimal medium + 44 μg/ml. uracil with 0·2 per cent glycerol as carbon source. Upper curves, *O.D.*; middle curves, DNA (assayed as described in Fig. 1); lower curves, OTCase activity (assayed as previously described[3]). At 0 min 22 μg/ml. FUdR was added to half the culture. Open circles (dashed lines) + FUdR. Closed circles (solid lines) without FUdR

periodic and the synthetic periods in the two cultures remained in phase.

The fact that periodic enzyme synthesis can continue for at least two cycles after DNA synthesis has ceased demonstrates that the initiation of synthetic cycles is not dependent on continued gene replication.

Repression and the Timing of Enzyme Steps

It has been reported in previous papers[1,2,4] that genes are potentially active at all times during the bacterial cell cycle. This was inferred from the observation that the rate of specific enzyme synthesis in synchronous cultures can be greatly increased at any time by the addition of inducer or removal of repressor. Evidence that genes are in fact always active, albeit at a low level, is provided by the observation that enzyme synthesis is continuous when the level of repression is constant. For example, the basal synthesis of alkaline phosphatase (APase) in the presence of excess inorganic phosphate has been shown to be linear with doublings in rate once per cell cycle[2,3]. Similarly, the basal synthesis of the inducible enzyme sucrase (in the absence of sucrose) is continuous in slowly growing cultures (Fig. 3).

However, in cultures in which sucrose is provided as sole carbon source, the synthesis of this enzyme is periodic (Fig. 3). This is consistent with the hypothesis that the catalytic action of sucrase on sucrose results in repressor (catabolite) production and the consequent feedback on enzyme synthesis gives an oscillating system.

In the normal cell cycle, periods of enzyme synthesis occur once in every cycle[1,2,4]. If there is a fixed period during which a particular enzyme may be synthesized, steps in enzyme amounts should occur at intervals equal to one cell cycle. It should not be possible to have steps initiated at smaller intervals than this. However, if oscillations in repressor concentrations underlie the periodic enzyme synthesis, it should be possible to upset the timing of enzyme steps by experimental interference with repressor-levels.

This was done in the following manner. The synthesis of ATCase in a synchronous culture was repressed by the addition of uracil. Since ATCase activity is unstable[3] the amount of active enzyme decayed progressively in the presence of uracil (Fig. 4). Aliquots were derepressed by washing free of uracil at 0·5 and 1·0 cell cycles after repressor addition. (Growth was not affected by this treatment.) In both aliquots ATCase synthesis recommenced

immediately on removal of uracil and rose rapidly until it reached the normal level for cells growing in the absence of external uracil. Synthesis then stopped and did not recommence for a further 40 min; 30 min (0·5 cell cycles) also separated the times of initiation of the second autogenous step in the two cultures (Fig. 4). The timing of OTCase steps (in these cultures) was not affected by the treatment. The initiation of steps in synthesis of ATCase and OTCase normally occurs simultaneously[4]. This experiment shows that the addition and removal of uracil at different times can result in the displacement of ATCase steps relative to one another and to OTCase steps. Thus release of repression can result in a specific alteration in the timing of subsequent autogenous enzyme steps.

A similar effect has been observed during the derepression of alkaline phosphatase (APase) (Fig. 5). The synthesis of this enzyme is discontinuous after removal of inorganic phosphate from the medium. Probably the cessation of synthesis after removal of external repressor results from the release of inorganic phosphate from an internal source. That *subtilis* has such an internal supply of phosphate is suggested by the fact that growth continues for a period after removal of all external inorganic phosphate.

As in the experiments on derepression of ATCase, the second initiation of enzyme synthesis occurred at a fixed time after the removal of repressor from the medium. Thus there is no fixed time in the cell cycle during which steps in APase are necessarily initiated. Thus we suppose that synthesis of APase is autogenous[2] for a period after removal of external supplies of repressor.

These experiments show that the repressor level can determine not only whether or not periodic enzyme synthesis occurs but also the time in the cell cycle at which the enzyme steps are initiated.

The experiments described here show that periodic enzyme synthesis in *Bacillus subtilis* does not require continued gene duplication and that the timing of the synthetic periods can be specifically altered by the addition and removal of repressor. It was previously shown[1,2,4], and is confirmed here, that enzyme synthesis can be initiated at any time in the cell cycle by removing repressor and that enzyme synthesis is not periodic in the presence of constant repressor levels. Taken together, these experiments strongly suggest that the basis of periodic enzyme synthesis in this organism is cyclic variation in repressor concentrations. It is supposed that these oscillations are self-generating[7] and arise from the feedback of end-product concentration on enzyme synthesis.

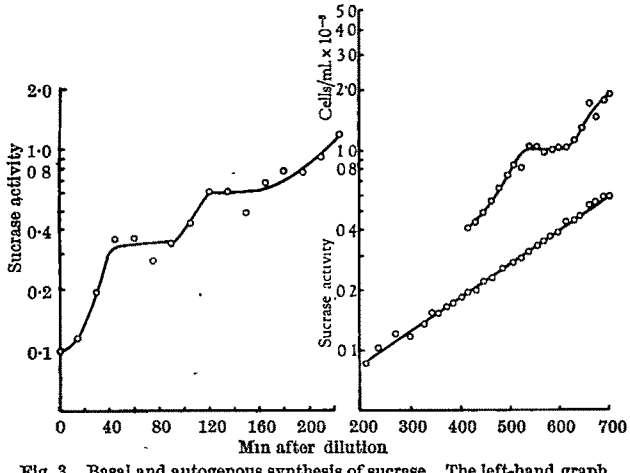

Fig. 3. Basal and autogenous synthesis of sucrase. The left-hand graph shows sucrase activity of *W*23 growing on minimal medium with 0·2 per cent sucrose as carbon source. The right-hand graph shows cell counts (upper curve) and sucrase (lower curve) of *W*23 growing on minimal medium with 0·2 per cent L-histidine as carbon source. The generation times were approximately 100 min on sucrose and 180 min on histidine. Sucrase was assayed as reported previously[1]. The units on the ordinates are arbitrary and are not directly comparable between the right and left graphs. Sucrase activity in the presence of sucrose is approximately 20-fold higher than in histidine cultures. The abscissa shows time in minutes from re-inoculation of the cultures from stationary phase

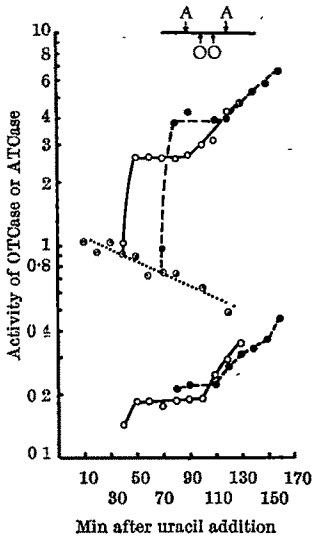

Fig. 4. Effect of uracil addition and withdrawal on the synthesis of ATCase (upper curves) and OTCase (lower curves) in a synchronous culture of *W*23. At 10 min, 2 × 10^{-4} M uracil was added to a synchronous culture of *W*23 growing on minimal medium + glycerol. Circles with central points represent ATCase in this repressed culture. At 40 min (open circles, solid lines) and 70 min (closed circles, dashed lines) 50 ml. portions were washed rapidly by filtration with minimal medium without carbon source at 37° C. The washed cells were resuspended in minimal medium + glycerol (without uracil) and sampling continued during subsequent growth. 5-ml. samples were taken into 50 μg/ml. chloramphenicol in ice, centrifuged and resuspended in 0·5 ml. of 80 μg/ml. cetyl trimethyl ammonium bromide

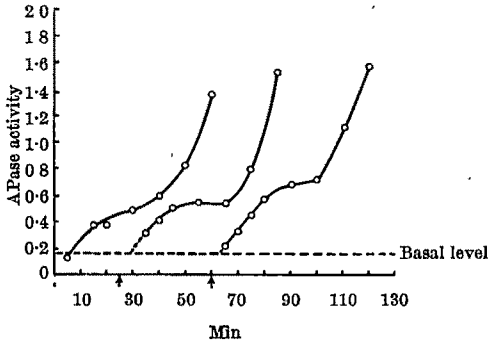

Fig. 5. Derepression of alkaline phosphatase. A stationary phase culture of 23*TR* was re-inoculated into low phosphate (2·5 × 10^{-5} M) minimal medium with 0·2 M *tris*, *p*H 7, + 0·2 per cent glycerol. The doubling time was 175 min. At the times indicated (arrows) 20 ml. portions were removed and washed free of phosphate by filtration with warm (37° C) minimal salts medium containing 0·2 M *tris* (*p*H 7). The cells were resuspended in this phosphate-free medium + glycerol. One-ml. samples were taken for enzyme assay, into 50 μg chloramphenicol in ice, during subsequent growth. The cells were lysed with lysozyme (0·1 mg/ml.) and 0·5 ml. aliquots incubated with 0·013 M *p*-nitrophenyl phosphate and 0·33 M ethylamine, *p*H 10·2, in a final volume of 1·5 ml. After incubation at 37° C, 0·5 ml. of 1 M potassium phosphate + 1 M sodium hydroxide was added to stop the reaction. Samples were centrifuged and the *O.D* at 405 mμ of the supernatants determined

These experiments suggest that periodic enzyme synthesis need not be restricted to organisms in which DNA synthesis is sequential and occupies the greater part of the cell cycle. Indeed, it is possible that similar cyclic enzyme synthesis will be found in any organism in which end-product repression occurs. Such cyclic synthesis has been predicted on theoretical grounds[7] and may have great importance in the development of differentiating organisms.

The apparent correspondence between order of enzyme syntheses and order of genetic replication requires explanation. In the model proposed by Pardee[6] periodic enzyme synthesis would continue for several cycles after gene replication had ceased. Goodwin[12] has devised a modification of this model in which 'free' periodic enzyme synthesis

is entrained to the period of gene replication by the synthesis of a small amount of messenger at the time of gene duplication. This model could explain the correspondence between genetic order and order of enzyme syntheses and, in principle, it can be tested.

The previous suggestion[3] that the instability of certain enzymes could result in stepwise increases in activity is now seen to be only part of the explanation. However, enzyme instability when it does occur will contribute to the discontinuous increase in enzyme amount, no matter what the cause of the initiation of the synthetic periods.

In summary, periodic enzyme synthesis in synchronous cultures of *Bacillus subtilis* continues in the absence of DNA synthesis and is therefore not directly dependent on periodic gene replication. The addition of repressor prevents periodic synthesis and its removal results in an immediate resumption of synthesis. The time of repressor removal and not the stage in the cell cycle determines the timing of the next period of enzyme synthesis.

AN ENTRAINMENT MODEL FOR TIMED ENZYME SYNTHESES IN BACTERIA

By Dr. B. C. GOODWIN*

Institute of Animal Genetics, University of Edinburgh

DETAILED analyses of enzyme dynamics in synchronously dividing cultures of micro-organisms have recently been reported[1–5]. These investigations have established the following points regarding the temporal ordering of events during the cell cycle in *E. coli* and *B. subtilis*. (1) Enzymes which are not continuously repressed double in activity suddenly at a characteristic time in the division cycle. (2) Repressed enzymes are synthesized continuously at low rates which double once every cycle. (3) Repressed enzymes can be induced at any time in the division cycle. (4) The normal doubling of an enzyme can be arrested by adding repressor, enzyme activity increasing when the repressor is removed. (5) The relative positions of steps for two different enzymes can be reversed by delaying the first enzyme with exogenous repressor and releasing it from repression after the second enzyme has doubled. (6) The potential for synthesis of a particular enzyme changes discontinuously at a characteristic time in the division cycle, which is not necessarily the same as the time of discontinuous enzyme synthesis. (7) The temporal sequence of doubling of potential for enzyme synthesis has the same linear order as the genetic map of the enzyme loci investigated (*E. coli*). (8) The temporal sequence of discontinuous enzyme bursts described in (1) is, on the average, the same as the sequence of enzyme loci in the genetic map (*B. subtilis*).

An obvious model relating the order of events during the cell cycle to the linear order of genetic loci postulates the transcription of genetic information temporally in the same fixed linear order as the spatial ordering of the genes. This model is attractive for its simplicity, but it is deficient in two respects. If genes can be transcribed only in a fixed sequence, then it should not be possible to (i) induce or derepress an enzyme at any point in the cell cycle, and (ii) reverse the order in which two enzyme steps occur during the cell cycle. It is thus necessary to seek alternative models which can explain all the observations so far, and also make some predictions which are subject to experimental test.

Observations (1)–(5) indicate that the enzyme steps which occur during the cell cycle are intimately connected with the operation of feedback repression circuits. One of the major dynamic consequences of negative feedback is the possibility of oscillations occurring in the variables involved in the control circuit. An extensive investigation of such oscillatory behaviour in the feedback repression circuits of resting or steady-state cells and the general consequences of such behaviour for the temporal organization of the cellular processes was made by Goodwin[6]. It will now be shown how timed enzyme syntheses in a population of synchronously dividing micro-organisms can be understood and analysed in terms of the same general dynamic principles, and how oscillatory behaviour and non-linear interaction can explain the phenomena already described. An explanation of discontinuous enzyme synthesis which introduces oscillations in feedback repression circuits has also been proposed by Kuempel *et al.*[2] and by Pardee[7].

Control Dynamics in Growing Cells

A set of relatively simple equations describing the operation of a closed feedback repression loop consisting of *m*RNA, enzyme, and enzyme product (repressor) can be derived making the following assumptions: (*A*) *m*RNA is the controlling factor for protein synthesis. (*B*) Enzyme is the controlling factor for production of enzyme product. (*C*) Repression of *m*RNA synthesis by enzyme product follows the same laws of surface adsorption as does enzyme inhibition.

Expressing *m*RNA concentration as X_i, enzyme as Y_i, and enzyme product as Z_i, the equations describing the dynamics of feedback repression can be written, on the above assumptions, in the form:

$$\frac{dX_i}{dt} = \frac{\lambda_i T_i}{\mu_i + K_i Z_i^n} - \nu_i X_i$$

$$\frac{dY_i}{dt} = \alpha_i X_i - \beta_i Y_i$$

$$\frac{dZ_i}{dt} = \rho_i Y_i - \gamma Z_i - \sigma_i$$

The Greek letters are all constants, γ being the constant of exponential growth of the cells, $\frac{dV}{dt} = \gamma V$. If the enzyme is stable then $\beta_i = \gamma$. σ_i is the rate of utilization of end-product Z_i per unit cell volume for growth. T_i is the concentration of the ith gene in the bacterial population, and n is the power of the repression (henceforth taken to be 1). Similar control equations have been derived previously[6,8,9].

These equations are complete (autonomous) except for the definition of how the quantity T_i varies in time. Keeping T_i constant, the equations define the dynamic behaviour of the repression circuit in cells which are growing but are not replicating their DNA, as occurs when 5-fluoro-deoxyuridine (FUdR) is added to a culture,

* Present address: School of Biological Sciences, University of Sussex, Falmer, Brighton, Sussex.

for example. There are two possible general modes of stable dynamic behaviour which such a system can show. In the first case the variables settle down after a longer or shorter period of damped oscillations to their steady-state values and remain there. This mode does not involve continuous oscillations in the variables. The other stable mode of dynamic behaviour is oscillatory: the variables X_i, Y_i and Z_i undergo continuous oscillations, all of the same period but of differing amplitudes. about their steady-state values. The mode into which the control circuit goes depends on the relative values of the parameters. Although rhythmic variation in molecular populations have been widely demonstrated in protozoa and the cells of higher organisms[10–14], there has been little evidence to suggest that bacteria have endogenous rhythms (see, however, Dimmick[15]). However, the latest results of Masters and Donachie[5] provide strong evidence for autonomous periodicities in bacterial control processes. The assumption of oscillatory behaviour in bacterial feedback repression leads to a consistent intepretation of these results and provides a useful working model for cell division in general.

Consider first the behaviour of the variables X_i, Y_i and Z_i in cells which are synthesizing all molecular species (RNA, protein, metabolites, etc.) but without DNA replication. In the oscillatory mode and with the parameters scaled roughly to give relative biological quantities of the variables, non-linear oscillations such as those in Fig. 1 can be observed on an analogue computer[9]. All variables are then periodic functions of time so that, for example, $Y_i(t + T)$ is equal to $Y_i(t)$, T being the period of the oscillation which is the same for all three variables X_i, Y_i and Z_i. If the variable $N_{Y_i} = Y_i V$ is plotted on a semi-log plot, one obtains the graph shown in Fig. 2. This shows steps in the total number of enzyme molecules in the culture (compare Masters and Donachie[5], Fig. 2).

If there are several feedback repression circuits operating simultaneously in a cell growing without DNA replication, then we might expect to have a situation such as that shown in Fig. 3. Here only the enzymes, Y_i of the repression circuits are shown, and only three of these are considered. In a bacterial cell there may be as many as 100 or more feedback repression circuits, all of which could show oscillatory behaviour. No interactions are assumed to occur between these circuits, and the variables in Fig. 3 run freely with periods which are assumed to be approximately but not exactly equal. Since the periods of the individual variables are not equal, the enzymes do not maintain constant phase relationships with each other. Y_2 and Y_3, for example, reverse their phase relations in two to three cycles. It is a prediction of this model that cessation of DNA synthesis would result in phase reversals of this kind, with no fixed linear order of enzyme steps. When DNA replication is allowed to proceed in the cells, sequential enzyme syntheses should occur, and a simple model will now be proposed which has this consequence.

Oscillator Entrainment by Replicating Genes

Assume that when that part of the DNA coding for a particular enzyme is replicated there is a small burst of messenger synthesis. Hanawalt and Wax[16] have concluded

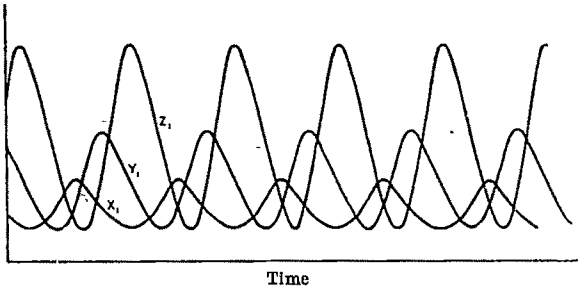

Fig. 1. Oscillations in the variables X_i, Y_i and Z_i

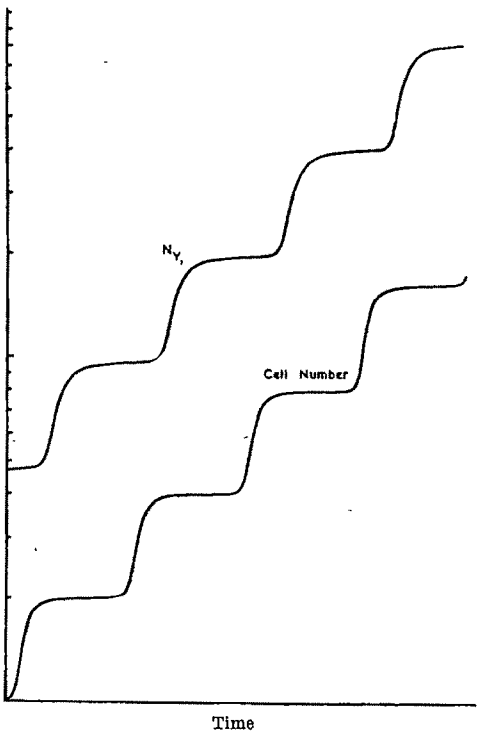

Fig. 2. [Steps in the variable $N_{Y_i} = Y_i V$ on a semi-log plot

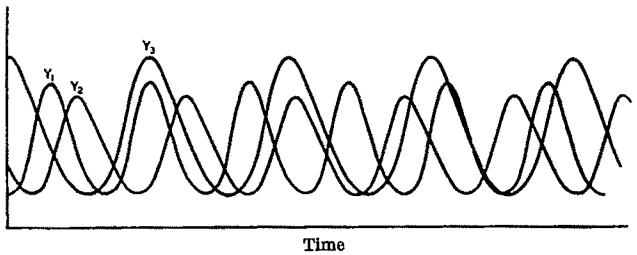

Fig. 3. Enzyme components of three feedback repression loops running freely in the absence of DNA replication

from their observations on the β-galactosidase system that such synthesis occurs at the moment of replication of the β-galactosidase gene in *E. coli*. If the doubling time of the culture is about 1 h and the DNA is replicated once every doubling time, then the frequency of these small bursts of *m*RNA synthesis at any locus will be also about one per hour. For any particular oscillating control circuit, such as that shown in Fig. 1, the effect of this burst is to add an additional small quantity of messenger X_i to the system as a pulse at regular intervals.

One of the commonest phenomena to occur in the interaction of non-linear oscillators is synchronous locking or entrainment of frequencies. In biology the best-known examples of this phenomenon are to be found in the literature on biological clocks, the most striking cases arising in the entrainment of circadian rhythms in organisms by light signals (Pittendrigh and Minis[17]). In a similar manner, the two periodic processes which we are considering here, DNA replication and oscillations in a closed feedback circuit, can lock together at the same frequency when they interact. In this event the interaction occurs because one of the variables is the same in both systems, namely, *m*RNA. The locking, or 'entrainment', will occur only if the frequency of the control circuit oscillations is sufficiently close to that of DNA replication, so that this must be assumed.

This entrainment phenomenon will occur for each control circuit which is operating and oscillating in the cell. However, the small bursts of *m*RNA synthesis which are assumed to occur when each gene locus is replicated

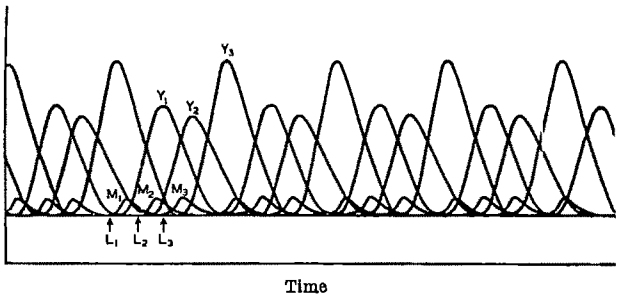

Fig. 4. Enzyme components of three feedback repression loops entrained by pulses of *m*RNA

will have a definite time order corresponding to the linear ordering of the genetic loci on the chromosome, since replication occurs linearly. The entrained control circuits will have the same temporal ordering, so the result is as shown in Fig. 4. This figure has been redrawn from results obtained on an analogue computer simulating the system. The small oscillations labelled M_1, M_2 and M_3 are the bursts of *m*RNA synthesis occurring just after the genetic loci replicate, three of which (L_1, L_2 and L_3) are represented as replicating at the times shown by the arrows. Only the enzyme components of the entrained control circuits have been shown in this figure. In comparison with Fig. 3, it is clear that the entrainment process imposes a definite temporal order on the enzyme oscillations and the linear relations of the genetic code are preserved in the phase relations of the oscillations. However, the non-linear interaction between the *m*RNA bursts and the control circuit operation resulting in entrainment is subject to disturbance by interference with the dynamics of the system, for example by altering repressor concentrations as described by Masters and Donachie[5]. There is also a finite probability that the control circuits will escape intermittently from the entrained condition so that spontaneous reversals of enzyme order can occasionally occur, as observed by Masters and Pardee[4] for the case of histidase and ATCase in *B. subtilis*. This entrainment model thus predicts a more labile dynamic behaviour than would occur in a deterministic tape-reading model.

It should be observed that there is an appreciable lag between the replication of any particular locus and the peak of the enzyme oscillation. If DNA replication occurs in a time period less than the cell cycle, then steps in enzyme synthesis occurring after DNA replication has ceased are to be expected, because of the dynamic time lags in the model. For example, if DNA synthesis takes only 46 min between L_1 and L_3, with L_3 the last locus to be replicated, then a step in Y_3 synthesis will be located at a point in the cell cycle some 20–30 min after DNA synthesis has ceased.

The model as it now stands can account for all the observations on the behaviour of enzymes and enzyme potentials which were summarized in the introductory paragraphs, and it makes some predictions. One is the drift in enzyme steps relative to one another when DNA replication is arrested in a culture, as shown in Fig. 3. Another consequence of this model distinguishes it from any model which postulates damping in the oscillations. The data so far available on enzyme dynamics in synchronously dividing populations of micro-organisms do not allow one to decide between these alternatives, since the number of steps observed is never more than three or four. Under chemostat conditions, however, the present hypothesis predicts that continuing periodicities should be observable in cell variables, and experiments are in progress to test this point.

A final prediction of this treatment of enzyme dynamics in bacterial cultures is that if continuing periodicities occur under chemostat conditions, then the synchrony maintained in the culture must be due to the transmission of some signal (or signals) between the cells. This is because a population of non-interacting oscillators, each subject to random variation, will quite rapidly drift out of phase with one another, even if they all have the same mean frequency. Some interaction between the control circuits of different cells would be required to keep the oscillations in phase, and a reasonable class of candidates for this interaction signal is the repressors themselves.

EFFECT OF CARZINOPHILLIN ON BACTERIAL DEOXYRIBONUCLEIC ACID: FORMATION OF INTER-STRAND CROSS-LINKS IN DEOXYRIBONUCLEIC ACID AND THEIR DISAPPEARANCE DURING POST-TREATMENT INCUBATION

By ASAHARU TERAWAKI* and DR. JOSEPH GREENBERG†

Palo Alto Medical Research Foundation, Palo Alto, California

PREVIOUS investigations with carzinophillin (CF), an antibiotic isolated from *Streptomyces sahachiroi* by Hata *et al.*[1], demonstrated its antibacterial activity as well as its marked anti-tumour effect in rodents[2]. In 1963, Endo *et al.*[3] reported that carzinophillin (CF) was able to induce λ-phage in *Escherichia coli*.

This article presents evidence that: (1) *E. coli* B_0, a strain sensitive to CF, shows a marked inhibition of DNA but not of RNA or of protein synthesis when treated with CF at doses that inhibit colony formation; (2) treatment of DNA of *E. coli* B_0 and of *Bacillus subtilis* results in formation of inter-strand cross-linking; (3) the CF-induced cross-linking effect disappears either in cells or *in vitro* during post-treatment incubation; (4) transforming activity of *B. subtilis* DNA, which is inactivated by this antibiotic, can be reactivated to some extent by post-treatment incubation *in vitro*.

Bacterial strains. *E. coli* B_0, a strain highly sensitive to mitomycin *C*[4] and CF but not to ultra-violet radiation and showing host cell reactivation, was used. *B. subtilis* strain 19 and strain 168 were a gift from Dr. D. Bobb of

† U.S. Public Health Service Career Development Award.

the Palo Alto Medical Research Foundation. Samples of carzinophillin were kindly provided by the Kyowa Fermentation Industry Co., Ltd., Tokyo, Japan.

Determination of nucleic acids and protein. Exponentially growing cells of *E. coli* B_0 at a density of 1×10^8 cells/ml. were incubated with shaking at 37° C in minimal glucose-salts medium (M9) containing various concentrations of CF. 10 ml. of the sample were taken at intervals and analysed for nucleic acids and protein. RNA was assayed by the orcinol reaction[5], DNA by the diphenylamine reaction[6], and protein by the Folin reaction according to the method of Lowry *et al.*[7].

Transformation assays. These were carried out with an indole-requiring mutant of *B. subtilis*, strain 168, by the method of Nester and Lederberg[8].

The 'irreversibility' of thermal denaturation was demonstrated spectrophotometrically in 7·2 M sodium perchlorate according to the procedure of Geiduschek[9]. Denaturation experiments were performed in the following manner. DNA solutions (20–30 μg/ml.) were heated to a given temperature in a thermostatic cell compartment of a spectrophotometer and the absorbance (A) at 260 mμ was measured after equilibrium was attained. The heated cuvettes were then plunged into ice for 45 sec, transferred to water at 25° C for 20 sec, rapidly dried and transferred to a second spectrophotometer maintained at room temperature and the absorbance again measured. The heating and quenching cycle was repeated at successively higher temperature. Absorbance at 260 mμ, measured at increasing temperatures, yielded curves marked (*d*) in Figs. 2–4, while measurement at room temperature on quenched solutions yielded curves marked (*i*).

The DNAs used were prepared from exponentially growing cells of *E. coli* B_0 and *B. subtilis* 19, wild-type, by the method of Saito and Miura[10].

Fig. 1 illustrates the preferential inhibition of DNA synthesis by CF for *E. coli* B_0. When cells of *E. coli* B_0 were incubated in the presence of CF at doses that inhibited colony formation (the dose of CF that permitted 20 per cent of the colonies to form after 60 min incubation was 5 u./ml.), the amounts of DNA failed to increase during 60 min incubation; after 60 min it gradually decreased. However, the formation of RNA and protein was unaffected compared with that of untreated cultures.

During incubation with CF, the optical density of the surrounding medium at 260 mμ increased more than that observed with untreated cultures. The preferential inhibition of bacterial DNA synthesis by CF, accompanied by progressive and extensive breakdown of DNA as evidenced by the increase in optical density at 260 mμ, indicate that DNA is the primary target.

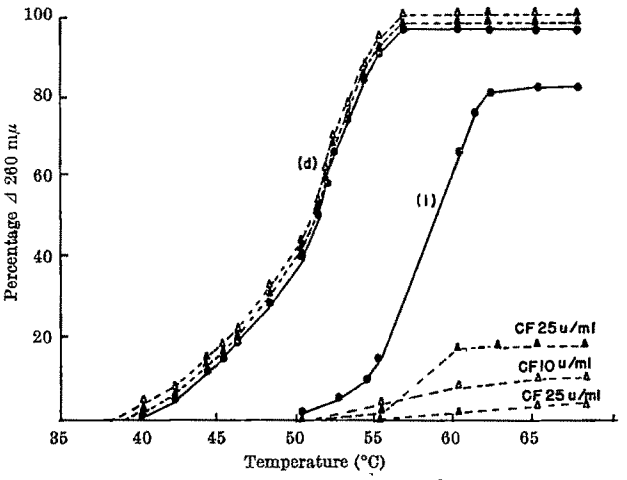

Fig. 2. Reversible thermal denaturation of CF-treated *E. coli* B_0 DNA:

$$\text{Percentage } \Delta 260\ m\mu = \frac{100\,(A(T) - A(25°))_i}{(A\ A\ \max)_d}$$

In vivo treatment of cells with CF: Cells cultured for 10 h in growing medium[17] were resuspended at a density of 2×10^8 cells/ml. in same medium containing 25 u./ml. of CF and incubated at 37° C for 30 min *In vitro* treatment of DNA with CF: 2·5 ml. of a solution of DNA (about 1 mg/ml) in 0·15 M sodium chloride plus 0·015 M sodium citrate was diluted 1 . 1 (v/v) with 0·14 M phosphate buffer (*p*H 7·0) containing CF. The mixture was incubated with gentle shaking at 37° C for 30 min. DNA was then precipitated by the addition of two volumes of cold 95 per cent ethanol, the precipitated DNA removed on a glass rod, drained, dissolved in 0·15 M sodium chloride plus 0·015 M sodium citrate, reprecipitated and redissolved. ——, Untreated DNA, – – – –, CF-treated DNA; △, *in vitro*; ▲, *in vivo*

It is known that other agents which specifically inhibit DNA synthesis, such as nitrogen mustard and mitomycin *C*, produce inter-strand cross-links in DNA as demonstrated by the reversibility of thermal denaturation[11,12]. To determine whether CF damaged the template DNA of *E. coli* B_0 in this manner, the reversibility of thermal denaturation of CF-treated DNA was investigated. Fig. 2 shows the results of denaturation experiments on CF-treated DNA.

Absorbance of DNA treated with CF both *in vivo* and *in vitro*, measured at the increasing temperatures ('standard' melting curves marked (*d*)), was very similar to that of untreated DNA, indicating no unstabilization of the DNA molecules such as follows deamination with nitrous acid[11]. With regard to the irreversible component (*i*), on the other hand, a change was observed. DNA treated with 25 u./ml. of CF *in vitro* was not irreversibly denatured at 65° C, at which temperature untreated DNA was almost completely denatured. Similarly, DNA extracted from CF-treated cells showed much less irreversibility than that of DNA extracted from untreated cells. These results are similar to those obtained with nitrous acid, nitrogen mustard[11] and mitomycin *C*-treated DNA[12], suggesting that, in CF-treated DNA, covalent cross-links between polynucleotide chains are formed.

It seemed reasonable that the presence of these cross-linkages in the DNA molecule was largely responsible for the biological effects

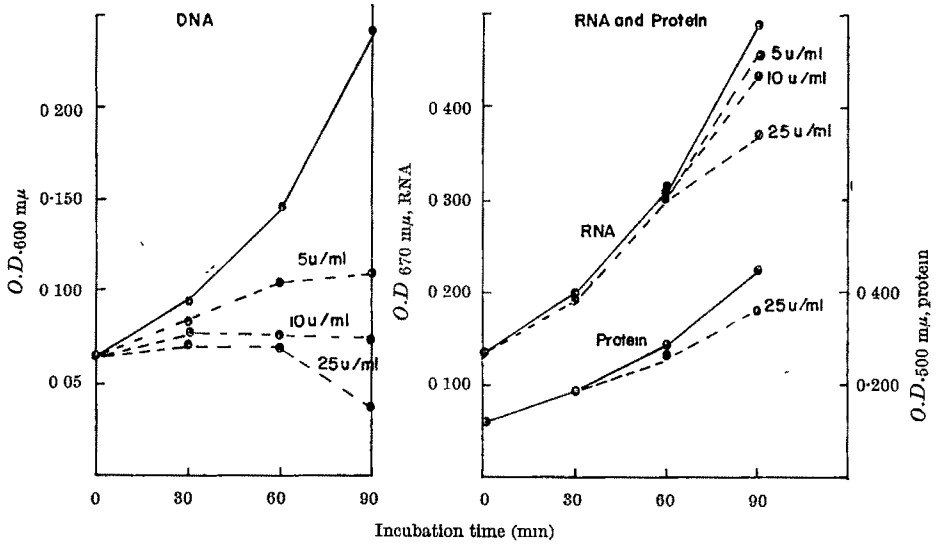

Fig. 1. Effect of CF on the synthesis of nucleic acids and protein ——, Untreated bacteria; – – – –, CF-treated bacteria

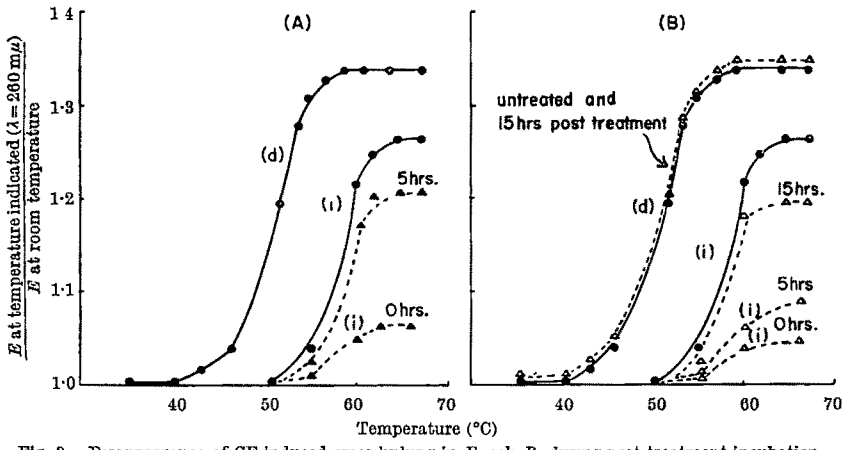

Fig. 3. Disappearance of CF-induced cross-linking in *E coli* B_0 during post-treatment incubation. *In vitro* post-treatment incubation was carried out as follows: after extraction of DNA from CF-treated cells, the solutions of DNA (200 μg/ml) in 0·15 M sodium chloride plus 0·015 M sodium citrate were incubated at 37° C for 5 or 15 h without shaking, and then subjected to thermal denaturation without reprecipitation. *In vivo* post-treatment incubation as described in text. ——, Untreated DNA, – – – –, CF-treated DNA; △, post-treatment *in vitro*; ▲, post-treatment *in vivo*

produced by CF. CF also has a filament-inducing action and the property of cross-resistance with mitomycin *C* and ultra-violet irradiation[13]. From these observations CF could be classified as a 'radiomimetic' agent along with poly-functional alkylating agents such as nitrogen mustard and mitomycin *C*. It has been shown that, during incubation, thymine dimers induced by ultra-violet irradiation were released into the acid-soluble fraction in several strains of *E. coli*[14,15]. Similarities in the biological effects between ultra-violet irradiation and radiomimetic substances imply that thymine dimers and the reaction products of radiomimetic substances and the DNA molecule might be handled in cells in a similar manner. For this reason the stability of CF-induced cross-linkages was investigated.

Cells of *E. coli* B_0 cultured for 10 h were treated with CF in M9 medium without glucose for 30 min at 37° C. The cells were then collected by centrifugation, washed and resuspended in the same medium, and incubated at 37° C for 5 h without shaking (*in vivo* post-treatment incubation).

DNA extracted from these cells, as shown in Fig. 3, showed partial restoration from the CF-induced effect to the normal state of DNA. During post-treatment also, incubation of extracted DNA (*in vitro* post-treatment incubation) for 5 h, a more limited disappearance of CF-induced cross-links than was seen with *in vivo* post-treatment incubation was observed. The same treatment for 15 h resulted in the disappearance of a large part of CF-induced cross-links.

It will be noted from the data in Fig. 3 that the absorption at 260 mμ of CF-treated DNA was unchanged after 15 h of *in vitro* post-treatment incubation. This observation could be interpreted to mean that the disappearance of CF-induced effect during post-treatment incubation *in vitro* is due to the splitting of cross-linkages in the DNA molecule *in situ*, because, if the disappearance of CF-induced cross-linkage occurs by excision of cross-linked nucleotides, a reduction in the rate of increase in the (*d*) curve should have been observed.

On the other hand, the rate of the disappearance of CF-induced cross-linking in intact cells was more rapid than that *in vitro*. This finding suggests the existence of some intracellular mechanism which is responsible for the recovery of DNA from CF-induced cross-linking effect. This interpretation is supported by the observation that, in several strains of *E. coli* showing host cell reactivation, mitomycin *C*-induced cross-linkages disappeared during *in vivo* post-treatment incubation, although the same treatment *in vitro* was ineffective[13].

It has been found recently that several sulphur mustard–DNA alkylation products are eliminated from DNA during post-treatment incubation *in vivo*[16]. In preliminary

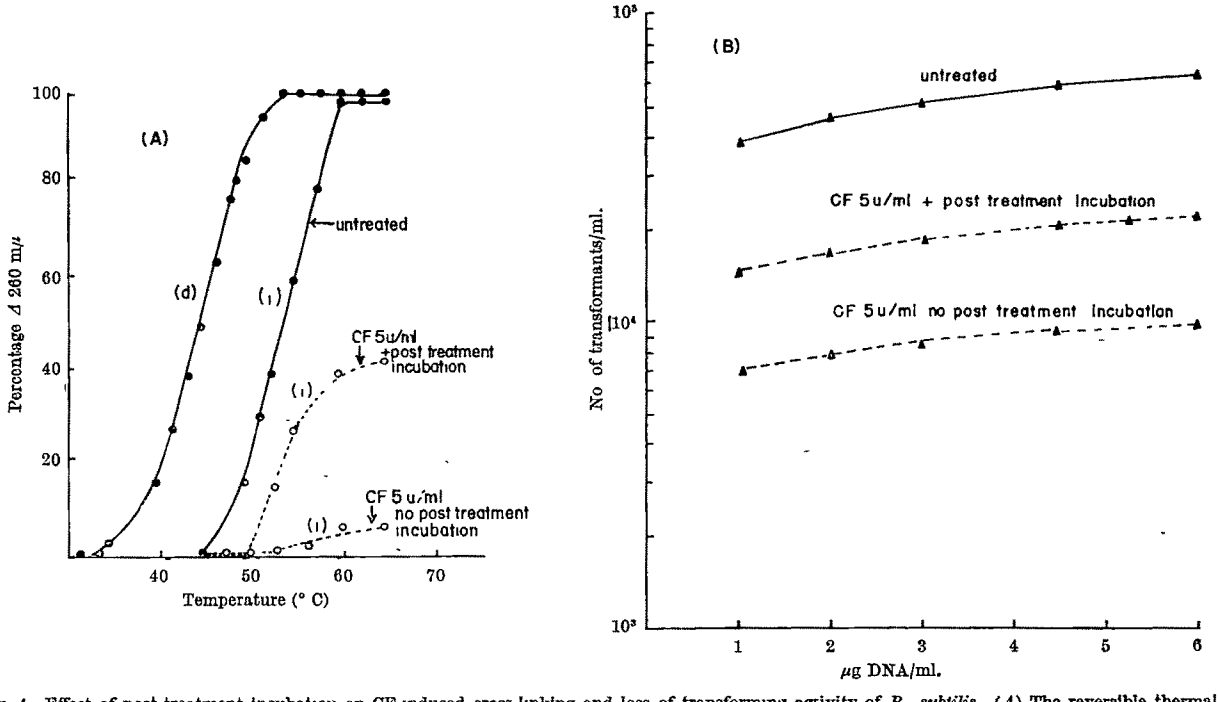

Fig. 4. Effect of post-treatment incubation on CF-induced cross-linking and loss of transforming activity of *B. subtilis*. (*A*) The reversible thermal denaturation of CF-treated *B subtilis* DNA and its reversal during post-treatment incubation. (*B*) The loss of transforming activity of *B. subtilis* induced by CF and its restoration during post-treatment incubation. In both experiments, same preparations of DNA were used. After incubation at 37° C the solutions of DNA were subjected to experiments without reprecipitation

experiments, we have also observed that, during post-treatment incubation of CF-treated cells, diphenylamine reacting material in the acid-insoluble fraction decreased and substances with an absorption maximum at 260 mμ in the acid-soluble fraction increased. Furthermore, the presence of glucose and casamino acid in the incubation medium enhanced the disappearance of the CF-induced effect. Such observations suggest that the elimination by excision of cross-linkages from CF-treated DNA occurs during post-treatment incubation *in vivo*.

We next investigated the possibility of the disappearance of the CF-induced DNA cross-linking effect during post-treatment incubation resulting in the reversal of the biological damage induced by CF. Fig. 4 (*A* and *B*) shows the result of experiments in which transforming DNA inactivated with 5 u./ml. of CF was subjected to *in vitro* post-treatment incubation. *B. subtilis* DNA reacted *in vitro* to CF under similar conditions and behaved in a manner analogous to *E. coli* B_0 DNA treated with this antibiotic with regard to the thermal denaturation. Transformation occurred at a frequency of 3·5 or 4·5 × 10^{-4} viable cells with the untreated transforming factor DNA (1 μg/ml.). Treatment of DNA *in vitro* with 5 u./ml. of CF for 60 min at 37° C reduced the transforming activity to about 15 per cent of the non-treated material. When the CF-treated DNA was incubated *in vitro* for 15 h, partial reversal of the DNA cross-linking effect and partial restoration of the decreased transforming activity of *B. subtilis* DNA were observed. This evidence implies a causal relationship between the cross-linking effect and the loss of transforming activity induced by CF.

We may, therefore, conclude that at least some of the biological effect of CF is mediated by the formation of inter-strand cross-linking in the DNA molecule. The *in vitro* reactivation system for damaged DNA is much simpler to investigate than that *in vivo*. Both inactivation and the subsequent reactivation occur in solution without any cell component.

Further investigations concerning the mechanism of the disappearance of cross-linkage *in vivo* are in progress to correlate our observations on the disappearance of cross-linking with DNA synthesis and mechanisms of resistance.

This work was carried out under U.S. Public Health Service grant *CA* 5687, National Cancer Institute.

CHANGES IN WALL TEICHOIC ACID RESULTING FROM MUTATIONS OF *Staphylococcus aureus*

By Dr. M. J. WOLIN*, Dr. A. R. ARCHIBALD and Prof J. BADDILEY, F.R.S.
Microbiological Chemistry Research Laboratory, Department of Organic Chemistry, University of Newcastle upon Tyne

TEICHOIC acids are closely associated with the surface structures of many Gram-positive bacteria. Representatives containing either ribitol or glycerol are found in cell walls[1] and glycerol teichoic acids are associated with the wall-membrane interspace, or the membrane itself[2,3]. The metabolic function of these polyol phosphate polymers in the bacterial cell is, however, unknown. There is evidence that at least some teichoic acid is covalently bound to the structural mucopeptide of the cell wall of Gram-positive bacteria, but it is believed that they are not necessary for the maintenance of rigidity of the wall structure. Synthesis of both mucopeptide and ribitol teichoic acids by intact *Staphylococcus aureus* cells is inhibited by penicillin[4], and it has been suggested that the teichoic acids might act as a foundation structure on which the mucopeptide is polymerized[5]. On the other hand, the lability in alkali of the D-alanine ester linkages to the polyol phosphate suggests a function for the teichoic acids which would involve the potential flexibility of the molecular charge, that is, at alkaline *p*H the molecule would lose alanine, become more negatively charged, and repulse anions, with the reverse situation operating at lower *p*H when the phosphate groups would be less ionized and the alanine could become positively charged.

Experimental evidence for the suggested functions of teichoic acids is almost non-existent, but the location of the teichoic acids in cells has reasonably restricted proposals to processes intimately connected with surface function or with the biosynthesis of the cell envelope.

* Present address: Department of Dairy Science, University of Illinois, Urbana, Illinois, U.S.A.

Mutants of *S. aureus* NCTC 8511 were recently described with phenotypic characters that are suggestive of difference between the surface structures of the mutants and the parent strain. We initiated an examination of the walls of the parent and certain mutant strains to determine whether structural differences in the teichoic acids occurred. It was thought that the mutants could provide a valuable experimental tool for investigating teichoic acid function if such structural differences were found. This article shows that the teichoic acid of certain mutants differs markedly from that of the parent strain.

The parent strain and mutants were obtained from Dr. Ruth Korman of Cornell University, Ithaca, New York. She has isolated and described the characteristics of the mutants, and some of the major phenotypic differences are summarized in Table 1. The fact that large phenotypic changes are associated with simple mutational events has been rationalized by the hypothesis that the phenotypic changes are caused by a primary change in the surface structure which leads to secondary changes in, for

Table 1. Phenotypes of Strains Studied
(Information taken from ref. 7)

Parent strain 8511	Glucose (+), lactose (+), mannitol (+), sucrose (+), fructose (+), galactose (+), 'Novobiocin'-sensitive, coagulase (+), phage-sensitive
Mutant *HS*635	Glucose (+), lactose (−), mannitol (−), sucrose (−), fructose (−), galactose (−), phage-sensitive, 'Novobiocin'-sensitive
Mutant *HS*968	Lactose (+), mannitol (−), sucrose (+), fructose (+), galactose (+), 'Novobiocin'-sensitive, phage-resistant, coagulase (−)
Mutant *HS*1160	Mannitol (+), fructose (+), sucrose (−), maltose (−), galactose (−), phage-resistant, 'Novobiocin'-resistant, coagulase (−)

Table 2. Major Components identified in Acid Hydrolysates

Products were identified by paper chromatography in: (*A*) propan-1-ol-aq. ammonia (sp. gr. 0·88)–water (6 : 3 : 1, by vol.); (*B*) pyridine–ethyl acetate–water–acetic acid (5 : 5 : 1 : 1, by vol.), (*C*) butan-1-ol–ethanol–water–aq. ammonia (sp. gr. 0·88) (40 : 10 : 49 : 1, by vol.; organic phase). Whatman No. 1 paper was used for descending chromatography. Products were detected where appropriate by the periodate-Schiff reagents for glycols[8,9], ninhydrin reagent for amino acids and amino sugars, molybdate-perchloric acid for phosphates[10] and aniline phthalate for reducing sugars[11]. Polyols were identified with solvent *A* and *C*

Strain	Products
8511	Ribitol, alanine, glucosamine, anhydroribitol, ribitol 5-phosphate, ribitol 3-phosphate, ribitol diphosphates
*HS*635	Ribitol, alanine, glucosamine, anhydroribitol, ribitol 5-phosphate, ribitol 3-phosphate, ribitol diphosphates
*HS*968	Glycerol, alanine, glucose, glycerol phosphates, glycerol diphosphates
*HS*1160	Glycerol, alanine, glucose, galactosamine, glycerol phosphates, glycerol diphosphates

example, permeability to sugars, susceptibility to attack by phage and sensitivity to antibiotics. A mutant similar to *HS*635 is known to have lost its ability to ferment several sugars simultaneously because of impaired permeability to sugars[6]. Korman reported[7] that the mutant *HS*968 has serine in its walls, whereas this is absent from walls of the parent strain.

Our first approach to the question of whether the teichoic acids of the mutants differed significantly from that of the parent strain was to determine the phosphorus content of walls prepared from each. The percentage of phosphorus (shown in parenthesis) in the walls of the various strains was: 8511 (2·64), *HS*1160 (3·30), *HS*968 (2·72) and *HS*635 (1·92). Although these differences may be significant, it was likely that all strains contained a wall teichoic acid. A qualitative examination of material extracted from the walls with 2 N hydrochloric acid for 24 h at 20°–22° C was carried out in a study of characteristic components of teichoic acid. The procedure was more vigorous than that generally used for extraction of these polymers, but this was convenient for the purpose of screening for major differences in components. The procedure did not remove components of mucopeptides from intact cell walls. The extracts were hydrolysed in 2 N hydrochloric acid for 3 h at 100° C and subjected to paper chromatography after appropriate deionization. The major sugars, polyols and amino acids in the hydrolysates are shown in Table 2. No changes were observed in the nature of the polyols when hydrolysates were dephosphorylated with an alkali phosphatase.

These results show that a major change in the teichoic acid of the cell wall occurs when mutants *HS*968 and *HS*1160 are derived from the parent strain 8511. Unlike the parent, there is no indication of the presence of a ribitol teichoic acid in the mutants *HS*968 and *HS*1160, but the chromatographic evidence strongly suggests that a glycerol teichoic acid is present in their walls. Mutant *HS*1160 can also be distinguished from mutant *HS*968 and the parent strain 8511 on the basis of the presence of galactosamine in the hydrolysed extracts.

Further support for the conclusion that these changes in the composition of the hydrolysed extracts actually represent changes in teichoic acids was obtained by extraction of teichoic acids from walls with trichloroacetic acid at 4° C, precipitation with organic solvents and partial purification by reprecipitation[12]. The polymers obtained in this way from walls of the parent strain and the mutant *HS*968 gave essentially the same products on acid hydrolysis (2 N hydrochloric acid, 100° C, 3 h) as did the 2 N hydrochloric acid extracts. However, hydrolysates of the polymer from trichloroacetic acid extracts of the mutant *HS*1160 contained no galactosamine. Wall residues from *HS*1160 obtained after extraction with 10 per cent trichloroacetic acid at 4° C for 2–24 h were subjected to further extraction with 2 N hydrochloric acid at 20° C for 16 h. The extract was treated with 2 vol. of acetone and kept at 4° C for 24 h. The resulting precipitate was collected by centrifugation, dissolved in 2 ml. of cold 5 per cent trichloroacetic acid and treated with 2 vol. of acetone. After 72 h at 4° C the precipitate was recovered by centrifugation and washed with ethanol, acetone and ether. The washed precipitate was dried in air and dissolved in water; insoluble material was removed by centrifugation, and the water-soluble portion was freeze-dried. This material was hydrolysed with acid, and chromatography of the products showed that they were the same as those for 2 N hydrochloric acid extracts of the walls, including the presence of significant amounts of galactosamine.

The acid hydrolysates of the polymers obtained from the parent and the mutants *HS*968 and *HS*1160 by extraction with trichloroacetic acid contain the typical products of hydrolysis of teichoic acids. The polymer containing galactosamine in *HS*1160, however, is not readily extracted with cold trichloroacetic acid but is extracted with 2 N hydrochloric acid at 20° C. The galactosamine is mainly in a fraction that also gives on hydrolysis typical glycerol teichoic acid components. However, it is not possible to decide at present whether a glycerol teichoic acid containing galactosamine occurs in *HS*1160 or whether the galactosamine is associated with other polymeric material. The extraction of material containing galactosamine in the 2 N hydrochloric acid fraction but not in the trichloroacetic acid fractions suggests that at least two polymeric species may be present. Treatment of wall residues of 8511 or *HS*968 with 2 N hydrochloric acid after the usual extraction with trichloroacetic acid resulted in the extraction of more polymer containing phosphorus, the hydrolysis products of which seemed to be grossly similar to those obtained by direct extraction with trichloroacetic acid.

The teichoic acids of the parent strain and mutant *HS*635 thus appear to be grossly similar to the teichoic acids of the *S. aureus* group, whereas *HS*968 and *HS*1160 have teichoic acids similar to those of the *S. saprophyticus* group[13] (classification according to Shaw, Stitt and Cowan[14]). Baird-Parker's recent classification of staphylococci and micrococci[15] records that staphylococci in his *Staphylococcus* Sub-group I are the only staphylococci which contain ribitol teichoic acid in the wall. The *Staphylococcus* Sub-groups II–VI of Baird-Parker have glycerol teichoic acids in their walls. No glucose is found in the walls of Sub-group I, but glucose occurs in walls from members of all the Sub-groups which contain wall glycerol teichoic acid. Members of Sub-groups II, V and VI, however, are the only staphylococci reported to contain galactosamine in their walls. Organisms in Sub-groups I and VI are the only ones with the ability to produce acid from mannitol. *HS*1160, the mutant which has glucose and galactosamine in the teichoic acid fraction, also produces acid from mannitol. *HS*968 does not ferment mannitol and does not have galactosamine in its wall teichoic acid. On the basis of the limited tests that have been performed, it would seem that *HS*968 is related to the organisms in Sub-group III and *HS*1160 related to organisms in Sub-group VI. It would be of interest to know whether strains of Sub-group VI yield wall teichoic acid fractions containing both glucose and galactosamine. Glycerol teichoic acids containing either glucose or galactosamine, but not both, have already been shown to be present in *S. saprophyticus*[13].

There are several interesting questions raised by the finding of fundamental differences in the composition of teichoic acids in mutants in addition to the question of the relationships of the mutants to natural strains of staphylococci. These experiments have shown that changes occur in the teichoic acids of mutants with other phenotypic differences suggestive of surface structure changes; but whether the other phenotypic differences are directly related to the changes in the teichoic acid is not known. The nature of the mutational event or events which account for the changes in wall teichoic acid is also obscure. That the phenomenon is complicated is evidenced by the fact that a change in the mucopeptide amino acids also occurs in *HS*968 (ref. 7). Moreover, the change from a wall ribitol teichoic acid to a wall glycerol teichoic acid

might appear to be a gain mutation. It is not necessary, however, to postulate such an unusual phenomenon to explain this change. All the Gram-positive bacteria examined contain membrane glycerol teichoic acid (as it is now known that so-called 'intracellular' teichoic acid occurs between the wall and the protoplast membrane and is attached, at least in part, to the latter structure it is proposed to call this 'membrane teichoic acid'), whether or not they have ribitol, glycerol or no teichoic acid in the wall[16,17]. It is possible that an event which leads to a loss of ability to synthesize or insert ribitol teichoic acid into the cell wall could simultaneously permit the insertion of a membrane teichoic acid into the wall. This hypothesis may be complicated by the necessity to postulate a control process to regulate the production of membrane teichoic acid and to prevent its insertion into cell walls of those organisms which either do not require a wall teichoic acid or which normally make a ribitol teichoic acid for this purpose. The hypothesis, however, does not involve the postulation of new genetic capability in the mutants containing wall glycerol teichoic acid because the capability for synthesis of glycerol teichoic acid exists in the parent strain.

ANATOMICAL RESPONSES OF PINE NEEDLES TO HERBICIDES

By Prof. T. T. KOZLOWSKI* and Dr. J. JOHANNA CLAUSEN
Department of Forestry, University of Wisconsin, Madison, Wisconsin

SEVERAL herbicides have shown variable toxicity to young gymnosperms, with susceptibility of plants varying greatly with the chemicals and dosage used, species, and age of plants[1–7]. Among the more obvious deleterious responses of young pine seedlings to herbicides are twisting and curling of cotyledons, distortion of old needles, chlorosis and subsequent death of the plant.

Although less obvious than the effects already noted, the influences of herbicides on internal leaf anatomy are often profound. For example, Ashton *et al.*[8] investigated the influence of atrazine on leaf structure in *Phaseolus vulgaris* and found that the herbicide: (*a*) accelerated development of vacuoles and modified ontogeny of chloroplasts in developing leaves; (*b*) ultimately caused chloroplast destruction and reduced the airspace system in mature and primary leaves; (*c*) promoted cessation of cambial activity and caused thin walls to develop in sieve and tracheary elements in the stem.

In another investigation, Ashton *et al.*[9] noted that atrazine induced several progressive changes in fine structure of chloroplasts in *Phaseolus*, including: (*a*) spherical rather than discoid shape; (*b*) disappearance of starch from the lamellar system; (*c*) destruction of frets leading to disorganization of the lamellar arrangement; (*d*) swelling of compartments of the grana; (*e*) ultimate disintegration of the swollen compartments. Ashton *et al.*[9] concluded that these changes were effected by formation of a toxic substance or substances involving interactions of light and atrazine in the presence of chlorophyll.

Only very few investigations are available that deal with anatomical changes induced by herbicides in woody plants. Parascan and Vlase[10] found marked variation among species in resistance to 2,4-D. *Betula*, *Carpinus betulus*, *Salix* and *Populus* were very sensitive to the herbicide. *Fagus silvatica* and *Quercus* were less sensitive, while *Tilia*, *Acer campestre*, *Acer tataricum* and *Prunus cerifera* were classified as resistant. The overall responses of plants to the herbicide were grouped into two categories: (1) decreased growth without dieback; (2) dieback. The first group was characterized by leaf modifications such as reduction in size, lobing, fasciation and, in isolated cases, epinasty. These changes occurred in the species generally resistant to herbicides. The second group responded by forming swellings and cankers, bark splitting, and wilting and dieback of shoots. Work with 3-amino 1,2,4-triazole by Shiue and Hansen[11] showed that the herbicide caused chlorosis, needle distortion, mesophyll collapse, and change in shape of mesophyll cells of *Pinus resinosa* and *Picea glauca*. These experiments have now been extended to an investigation of the influence of several herbicides on leaf anatomy of young pine plants.

Experiments were performed on young red pine (*Pinus resinosa* Ait.) plants. Herbicides were incorporated in the soil or applied as soil surface sprays according to the following schedule:

Herbicides incorporated in soil and applied pre-emergence: atrazine, simazine, prometryne, propazine, ipazine, EPTC, DCPA, CDEC, and CDAA. Each herbicide was applied at 2 or 8 lb./acre (surface area basis).

Herbicides applied to soil surface when plants were six months old: atrazine, simazine, prometryne, propazine, ipazine, EPTC, DCPA, CDEC, CDAA, monuron and diuron. Each herbicide was applied at 16 lb./acre.

For the soil incorporation experiments, Plainfield sand was placed in greenhouse flats to a 2 in. depth and the appropriate herbicide sprayed on the soil surface at 2 or 8 lb./acre. The soil and herbicide were then mixed in a Patterson–Kelly twin-shell blender and distributed in 4-in. clay pots. One hundred *Pinus resinosa* seeds were planted in each of ten pots for each dosage of each herbicide. Pots planted with seed but without herbicide served as controls. Seeds germinated regularly, beginning about 10 days after planting. For the surface application experiments, each herbicide was sprayed to the surface of soil in pots containing 6-month-old seedlings.

Eight weeks after application of the herbicides, representative needles of all plants were collected and preserved in formalin–acetic acid mixture. Afterwards the needles were embedded in 'Tissuemat', cross-sectioned at 12μ and stained with safranin and fast green before the sections were mounted on slides.

* Fulbright research scholar at the Department of Forestry, University of Oxford.

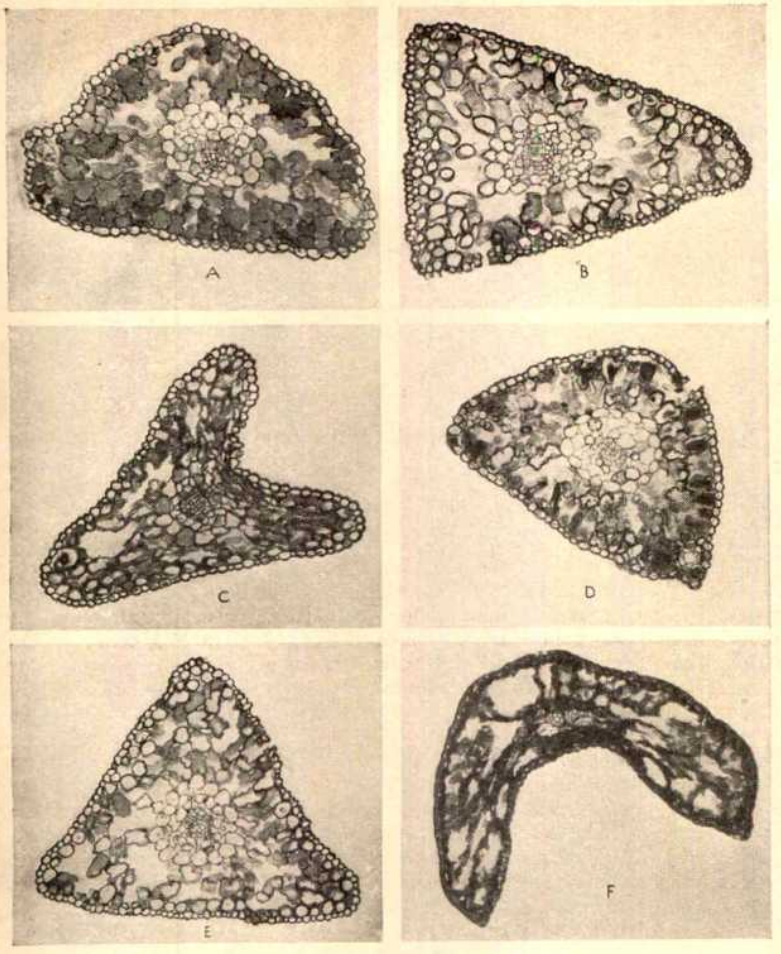

Fig. 1. Influence of various herbicides on young *Pinus resinosa* needles. *A*, Control (no herbicide). Needle semicircular in cross-section. Mesophyll cells are closely packed and infolded. *B*, CDAA incorporated in soil at 8 lb./acre (surface area basis), pre-emergence. Needle triangular in cross-section with granular, red-staining material in some mesophyll cells. Mesophyll cell contents often missing. Large gaps show among mesophyll cells. *C*, Prometryne incorporated in soil at 2 lb./acre (surface area basis), pre-emergence. Needle distorted and collapsed. Chloroplasts are not apparent and rounded mesophyll cells have large gaps among them. *D*, EPTC incorporated in soil at 8 lb./acre (surface area basis), pre-emergence. A normally shaped cross-section shows breakdown of chloroplasts. Red-staining granular material is present in mesophyll instead of solid red-staining chloroplasts. Mesophyll cells are frequently rounded and have spaces among them. *E*, CDEC incorporated in soil at 8 lb./acre (surface area basis). The triangular cross-section shows no red-stain in the mesophyll. Large gaps exist among rounded, frequently empty mesophyll cells. *F*, Diuron applied to soil surface at 16 lb./acre when seedlings were six months old. The typically brown needle was shrivelled. The mesophyll is totally collapsed and only the epidermis and some conducting tissues retained their normal form. (× 72)

Soil-incorporated herbicides caused far more injury than those applied to the soil surface. Within 10 days from the beginning of germination, toxicity symptoms were developing in plants growing in soil containing incorporated herbicides. In general, slight needle curling was followed by severe chlorosis, needle dieback, seedling distortion, depressed growth and death of many needles. Most injury was caused by atrazine, simazine, prometryne and propazine, whereas ipazine, EPTC, CDEC, CDAA and DCPA caused far less and sometimes only negligible injury.

The surface-applied herbicides fell into three groups. Atrazine, simazine, monuron and diuron were highly toxic. Prometryne, propazine, CDEC and CDAA caused intermediate damage, while EPTC, DCPA and ipazine caused slight to no obvious injury.

There was considerable variation among needles in the amount of injury sustained. When needles were severely damaged the internal anatomy was altered in a more or less similar way by the various herbicides. Such anatomical changes, however, covered a fairly broad spectrum within and among seedlings. Only generalized symptoms of herbicide effects on leaf anatomy are given at this stage, with further experiments contemplated to investigate details of variable injury by different herbicides.

Examples of sections of healthy and herbicide-damaged needles are shown in Fig. 1. Cross-sections of needles from control plants were approximately semicircular in outline. The mesophyll cells were closely packed and infolded and contained large, dark-red-staining chloroplasts. In contrast, the distorted needles of herbicide-treated plants showed considerable yellowing or browning, and were triangular (or nearly so) in cross-section. Many needles which had turned brown had shrivelled. The red stain of chloroplasts was very pale or absent and red-staining nuclei were thus unmasked. Mesophyll cells were predominantly rounded and had lost the characteristic infolding of normal mesophyll tissue. Mesophyll cells sometimes became vacuolated or nearly empty. Often conspicuous large gaps among mesophyll cells were apparent. In some needles red-staining granular material was present in the mesophyll. The cells of lignified epidermis and vascular bundles retained their outlines, but the mesophyll had disintegrated, permitting the needle to collapse. Sometimes only one of the three needle surfaces was concave as a result of mesophyll collapse.
